Credit Smoothing

May 4, 2019

Abstract

Standard economic theory says that unsecured, high-interest, short-term loans – such as borrowing via credit cards and bank overdraft facilities – helps individuals smooth consumption in the event of transitory income shocks. This paper shows that—on average—individuals do not use such borrowing to smooth consumption when they experience the typical transitory income shock of unemployment. Rather, it appears as if individuals smooth their roll-over credit card debts and overdrafts. We first use detailed longitudinal information on debit and credit card transactions, account balances, and credit lines from a financial aggregator in Iceland to document that unemployment does not induce a borrowing response at the individual level. We then replicate this finding in a representative sample of U.S. credit card holders, instrumenting local changes in employment using a Bartik (1991)-style instrument. The absence of a borrowing response occurs even when credit supply is ample and liquidity constraints, captured by credit limits, do not bind. This finding stands in contrast to the prediction of strictly countercyclical demand for credit by theories of consumption smoothing. On the contrary, demand for credit appears to be procyclical, which may deepen business cycle fluctuations.

JEL codes: D14, D90

1 Introduction

How does unsecured, high-interest, short-term borrowing respond to income shocks? Standard consumption models make a clear-cut prediction: if such credit is ever used, then it is used in response to adverse transitory income shocks.[1] However, empirical evidence for a strong borrowing response to transitory income shocks remains scarce. This can partly be explained by a lack of data containing accurate, high-frequency information on both individual credit use and income. Furthermore, disentangling the effects of the demand and supply of credit (adverse income shocks may increase demand but decrease supply) and transitory and permanent income shocks (the former should entice a borrowing response while the latter should not) is difficult.

In this paper, we seek to investigate and quantify how credit card and overdraft borrowing responds to a quintessential transitory income shock due to unemployment. We first use monthly data from a personal finance platform in Iceland (a "financial account aggregator"), containing comprehensive transaction-level information on individual spending, income, account balances, and credit limits, to investigate how expenditures, liquid savings, and consumer debt change upon temporary job loss. The longitudinal nature of our data allows us to include individual fixed effects in our estimations and thereby control for selection on all time-invariant (un)observables.

Using the financial aggregator data, we find that, over the average spell of unemployment, individuals reduce their spending, but do not increase their consumer debt holdings substantially, even if they borrow regularly and have sufficient liquidity. More specifically, we find neither an increase in the likelihood to have an overdrawn checking account nor the number of overdrawn checking accounts (even though the baseline probability of holding an overdraft is larger than 50%, i.e., the majority of individuals

---

[1]Unsecured debt or non-collateralized debt refers to loans that are not tied to any asset. In the U.S. and Iceland, unsecured debt consists primarily of credit card loans and overdrafts from current accounts.

in our sample borrow regularly). The data covers the period 2011 to 2017, a time of economic expansion over which unemployment was low and generally short-lasting. Unemployment in such circumstances is a quintessential kind of transitory income shock, which we confirm in the data by showing that income of individuals is not permanently affected by job loss. These findings thus suggest that large transitory income shocks are not a major driver of the substantial consumer debt holdings we observe and difficult to rationalize with unsecured high-interest borrowing being an important tool for smoothing consumption in the event of adverse transitory income shocks.

We then turn to U.S. household credit data from the Federal Reserve Bank of New York and the Equifax Consumer Credit Panel (CCP), covering the universe of credit card accounts nationwide from 2000 to the present, to confirm and replicate our findings. Constructing county-quarter measures of credit outcomes and employing a Bartik-style shift-share instrument as an exogenous source of variation in county-level employment, we produce estimates of the elasticity of equilibrium credit card account balances, limits, inquiries, and utilization.[2] We replicate our initial finding using the financial aggregator data in that we find no clear and significant changes in borrowing in response to unemployment shocks. More specifically, we find that individuals in counties with adverse unemployment shocks neither appear to increase their overall outstanding balances (even among those with a slack in their credit utilization ratios), nor do they appear to increase their inquiries for new credit relative to counties with less adverse unemployment shocks.

Because we do not observe individuals' incomes in the U.S. data, we complement this analysis by looking at the distribution of individual borrowing outcomes conditional on county-level unemployment shocks. Using quantile regressions, two facts stand out:

---

[2]The estimation and interpretation of causal effects using a Bartik-style instrument to isolate shocks to labor demand has been employed by a number of authors. An incomplete list of papers includes Blanchard et al. (1992); Gould et al. (2002); Aizer (2010); Nguyen et al. (2015); Chodorow-Reich et al. (2012); Maestas et al. (2016); Keys et al. (2017).

even amongst the top half of the conditional distribution, responses are economically small; and if anything, point estimates are in the "wrong" direction, i.e., the biggest quarterly borrowings do not reliably and positively respond to increases in unemployment. The largest increases in borrowing appear to occur regardless of the variation in unemployment as captured using county-level Bartik instruments. We thus conclude that, while average credit card balances in the U.S. are very high, most individuals do not increase credit card debt in response to unemployment, even when they could have done so and for unemployment shocks that are arguably transitory (for instance, during the financial crisis).

The 2015 American Household Credit Card Debt Study estimates the total credit card debt owed by an average U.S. household to be $15,762, which amounts to a total of $733 billion, and the average Icelandic household's amount borrowed is of similar magnitude. Such large high-interest debt holdings over longer periods of time are very hard to rationalize in standard economic models. E.g., Laibson et al. (2003) argue that such debt holdings constitute a puzzle for standard life-cycle models in which fully rational agents would rather forgo the benefits of consumption smoothing than borrow at such high interest rates. Laibson et al. (2017) show that a model with hyperbolic discounting and illiquid assets rationalizes the amount of borrowing we see in U.S. data. However, for the calibration to work, the hyperbolic-discounting parameter has to be half of what is commonly estimated in other domains (refer to, for instance, Kahneman et al., 1990) and agents have to be fully naive, i.e., they must believe that they will not have any hyperbolic discounting problems but are perfectly rational in all future periods. There also exist rational models that generate some borrowing in response to permanent income shocks in the presence of illiquid assets (Kaplan and Violante, 2014). However, Kaplan and Violante (2014) assume the absence of transitory income shocks, to which any rational agent would respond by holding a small buffer of liquidity.

Furthermore, they document that agents in the model bunch at zero borrowing when interest rates are high, such as the rates on credit cards or overdrafts, or they borrow but then up to their credit limits when interest rates are relatively low, such as the rates observed on home equity lines of credit.

Standard economic models say that credit demand should be countercyclical. We demonstrate this theoretically using the model by Laibson et al. (2017). In the event of an income shock calibrated to the Icelandic unemployment replacement rate, the hyperbolic agents in the model, calibrated to match the real-world borrowing on credit cards that we see, increase their likelihood to borrow by 31%, increase their amount borrowed by 319%, and decrease their spending by 7%. While the spending responses matches the data quite well, the strong borrowing response is clearly a counterfactual prediction of the model. It is important to note additionally, that any economic model in which individuals have a concave utility function and thus want to smooth consumption would predict a strong negative correlation between borrowing and income. However, empirically we conclude that households allow consumption to adjust while smoothing their debt balances and thus document an important discrepancy between our theoretical and empirical results.

As a broader implication, the credit smoothing we observe in the data will amplify business cycles compared to the countercyclical demand predicted by the economic models. While an extensive literature has explored supply amplifiers during the Great Recession, our paper suggests that we should also examine demand amplifiers during the initial expansionary and then contractionary period. Our results are consistent with household demand driving dynamics in consumer credit markets which relates our paper to the demand-side (Adelino et al., 2016) versus supply-side (Mian and Sufi, 2009; Mian et al., 2013) studies in the mortgage market. In the same manner as for mortgages (Mian et al., 2013), consumer credit may cause "debt overhang", creating

credit-driven business cycles that operate through household demand. In terms of policy implications, if unsecured, high-interest lines of credit such as credit cards do not appear to be used to smooth consumption, the self-insurance benefits are limited, and if individuals misunderstand the high costs, then government policy or education may have a role to play in affecting not only the supply of credit, but also its demand.

2 Literature review

The rapid growth in the use of consumer credit in recent decades has spurred a lot of interest in this area of research while recent improvements in data availability have made it possible to investigate this trend empirically. Müller (2018) documents that over the last 50 years, household credit has risen dramatically and consumer credit accounts for much of this growth rather than mortgage lending. Whether or not consumer credit is used as economic models suggest, i.e., a tool to smooth consumption and thus countercyclical, is debated empirically.

Several recent studies are on the "not countercyclical" side. Fuster et al. (2018), e.g., find consumption declines in surveys of hypothetical negative shock scenarios, and that these declines are similar even when the scenario includes an interest free loan. Hundtofte (2017) also finds evidence of self-imposed financial constraints in field data by observing voluntary credit card closures, and finds that these increase in response to negative economic news such as house price declines or unemployment. Furthermore, Baker and Yannelis (2017), Gelman et al. (2015), Ganong and Noel (2018), Olafsson and Pagel (2018a), and Olafsson and Pagel (2018b) show a lack of consumption smoothing in response to predictable positive and negative income shocks using transaction-level income and spending data. Baker and Yannelis (2017) and Gelman et al. (2015) analyze individual responses to a temporary shortfall in income due to the 2013 government

shutdown. Strikingly, despite the short nature and perfect certainty of this transitory income shock, Gelman et al. (2015) do not find an increase in credit card borrowing either but only find a mechanical increase in credit card debt due to the delay of credit card payments despite individuals having ample space to their credit limits. Individuals simply cut spending sufficiently and substitute to home production (shown in Baker and Yannelis, 2017) to get by. In this paper, we thus show that this lack of borrowing also generalizes to larger and longer-lasting but still temporary income shocks due to short spells of unemployment in a booming economy.[3] To the best of our knowledge, the effect of unemployment on the use of consumer credit using longitudinal, high-frequency, and accurate individual-level data including income and all financial account balances has not been undertaken before.

However, other recent studies argue that the demand for credit appears to be countercyclical and that individuals do indeed tap their credit lines when a rainy day comes their way or, if they do not, then because of liquidity constraints. Using survey data, Browning and Crossley (2009) and Sullivan (2008), for example, find that very low asset households as well as wealthy households do not increase their debt in response to unemployment, while the average effect for all other households is positive. The authors both argue that low asset households are credit constrained, which we can directly address in this study because we observe credit limits. Our findings are in contrast to Keys et al. (2017) who, using a similar but larger sample of unmatched (to the individual) credit card data and the same source of variation in employment with focus on the cross-sectional variation provided by the Bartik shock in the first quarter of 2008,

---

[3]Our findings are also consistent with those in Ganong and Noel (2018), who use transaction-level bank account data of one U.S. bank and show that, in their sample, borrowing increases by merely $23 two months after the onset of unemployment and by merely $45 two months after unemployment benefit exhaustion, even when individuals have substantial credit available. As the authors observe only checking and credit card accounts from one bank, they do not explore this lack of a borrowing response further.

conclude that consumer demand for credit card borrowing was countercyclical.[4] Another recent study is Braxton et al. (2018) who also show that job losers retain access to credit and that the average borrowing response as well as the effect on credit limits is zero. However, they argue that this zero result is due to unconstrained job losers borrowing (an increase in balances), while constrained job losers delever and default (a decrease in balances). We do not find an increase in borrowing by unconstrained job losers nor a substantial increase in delinquient balances in the U.S. data. Additionally, before defaulting, we would see individuals use their open credit lines. Furthermore, we virtually do not observe any defaults in the Icelandic data.[5]

3 Theoretical background

We consider the same model as in Laibson et al. (2017) to formally illustrate the standard predictions of how borrowing responds to income shocks in a life-cycle model that successfully explains the extent of credit card borrowing via illiquid savings and naive hyperbolic discounting (see, Laibson, 1997; O'Donoghue and Rabin, 1999; Kuchler and Pagel, 2015). Additionally, the model explains the existing evidence documenting a lack of consumption smoothing by showing that individual marginal propensities to consume out of transitory income shocks are very high (see Shapiro and Slemrod, 1995, among

---

[4]Efforts to replicate the findings of Keys et al. (2017) as closely as possible have revealed that the different conclusions can be explained by two important differences between the analyses. First, our results are based on individual-level observations while the analysis in Keys et al. (2017) is based on card-level observations aggregated up to the county-level and weighted by the base-period number of accounts in the county. If individuals with different number of cards behave differently, a different relationship should be reflected in different estimates from aggregating individual-level rather than card-level data. Secondly, Keys et al. (2017) focus on the cross-sectional variation of the Bartik employment shock in the beginning of 2008, examining various longer horizon outcomes in response to that shock, while we focus on shorter-run responses to employment shocks, pursuing a panel analysis of shocks over the period 2000 to 2016.

[5]If individuals in Iceland default they are enlisted in the official defaulters' list which prevents them from taking out new loans and opening up new credit cards for up to 4 years among other sanctions, therefore, defaulting has serious consequences while borrowing using existing credit lines does not.

many other studies). Beyond illiquid assets and naive hyperbolic discounting preferences, the model features revolving high-interest credit, liquidity constraints, stochastic labor income, social security, child and adult household dependents, retirement, and mortality. The authors estimate the preference parameters using the method of simulated moments; in particular, the exponential discount function of a standard agent as well as the present-biased discount function of a hyperbolic-discounting agent. The authors show that the standard model of exponential discounting can be formally rejected in favor of hyperbolic discounting. Nevertheless, the hyperbolic discount factor the authors estimate is relatively low in comparison to typical estimates and assumptions in the micro literature (see, for instance DellaVigna, 2009, for a literature survey).

More specifically, Laibson et al. (2017) consider the following model.[6] The agent lives for $t = \{1, ..., T\}$ periods. Each period the agent optimally decides how much to consume C_t. Additionally, he decides how much to save in the liquid and illiquid assets. X_t represents the beginning of period t liquid asset holdings before receipt of period t income Y_t. If $X_t < 0$ then uncollateralized high-interest debt, i.e., credit card debt, was held between t and $t-1$ at an interest rate of R^{CC}. The agent also faces a credit limit in period t of λ times average income at age t. If the agent saves instead of borrows, he earns an interest R. $Z_t \geq 0$ represents illiquid asset holdings at the beginning of period t, earning interest R^Z and providing consumption value. However, illiquid assets can be liquidated only with a proportional transaction cost, which declines with age $\kappa_t = \frac{1/2}{1+e^{t-50/10}}$. Let I_t^X and I_t^Z represent net investment into the liquid and illiquid assets so that the budget constraint is given by

$$C_t = Y_t - I_t^X - I_t^Z + \kappa_t min(I_t^Z, 0).$$

[6]We thank the authors for kindly sharing their solution code.

The consumer has constant relative risk aversion quasi-hyperbolic preferences and maximizes

$$max_{I_t^X, I_t^Z} \{ n_t \frac{(\frac{C_t + \gamma Z_t}{n_t})^{1-\rho}}{1-\rho} + \beta E_t [\sum_{\tau=1}^{T-t} \delta^\tau (\Pi_{j=1}^{\tau-1} s_{t+j})(s_{t+\tau} \frac{(\frac{C_{t+\tau} + \gamma Z_{t+\tau}}{n_{t+\tau}})^{1-\rho}}{1-\rho} + (1 - s_{t+\tau}) B(X_{t+\tau}, Z_{t+\tau}))] \}$$

each period t subject to the budget constraint. Here n_t represents family size in period t, ρ is the coefficient of relative risk aversion, β is a hyperbolic discount factor, and δ is an exponential discount factor. The agent is fully naive in the sense that his period t self does not take into account that his period $t+1$ self is present-biased. $B(\cdot)$ incorporates the bequest motive in the death state which is represented by $s_t = 0$ instead of $s_t = 1$ when the agent survives. More details can be found in Laibson et al. (2017) and the model is solved by numerical backward induction. Laibson et al. (2017) estimate the environmental parameters of the model using data from the American Community Survey of the U.S. Census Bureau, the Survey of Consumer Finances, and the Panel Study of Income Dynamics and the preference parameters of this model to match the patterns of wealth accumulation and credit card borrowing over the life-cycle and we adopt the parameters of their best fit for the hyperbolic agent. In turn, we consider a standard agent by setting $\beta = 1$.

We simulate the life-cycle consumption paths of 10,000 agents and then run the equivalent of our empirical specification in the simulated data; i.e.,

$$log(abs(X_{i,t})|X_{i,t} < 0) = \alpha + \beta I_{i,t}^{15} + age_{i,t} + \epsilon_{i,t}$$

where $log(abs(X_{i,t})|X_{i,t} \leq 0)$ is the amount borrowed by agent i at age t (set to zero if the agent does not borrow) and $I_{i,t}^{15}$ is an indicator variable if agent i's realization of income at age t is 67% or less than his income at age $t-1$. The income process is calibrated to include social security and unemployment benefits but does not specifically

9

model unemployment which is why we choose a low draw of income to represent a transitory income shock. Here, we take 67% as it represents the Icelandic unemployment insurance replacement rate. The simulation results are robust to modifying this cutoff; the lower the cutoff the more extreme the borrowing response. Furthermore, to eliminate life-cycle effects, $age_{i,t}$ is a set of age or cohort fixed effects. Alternatively, we can use an indicator for whether or not agent i at time t borrows as the outcome variable as well as log consumption. Because all agents are the same in the sample of simulated data, this regression is equivalent to our empirical specification with individual fixed effects. Of course, in reality, there does not only exist one type of agents but agents are heterogenous in their preferences. That is why we report the regression results for two types of agents: a hyperbolic agent, whose preference parameters are estimated by Laibson et al. (2017) using a representative sample of the U.S. population, and also a standard agent who does not have a hyperbolic discounting problem. If one were to observe a mixed group of these two agents, the coefficients would be a combination of the ones displayed.

As we can see in Table 1, having an income realization less than 67% the previous income implies a 31% and 319% increase in the likelihood and amount borrowed and a 7% decrease in consumption in the hyperbolic discounting model. We find that present-biased agents in the model are consumption smoothing as standard agents and use borrowing as a tool to smooth transitory income shocks. For the standard agent, the borrowing response is somewhat less pronounced but still positive and significant as the standard agent almost never borrows at the level of interest rates considered in this model. In fact, the standard agent only borrows 0.15% of the time.

[Table 1 about here]

10

4 Data

In this study, we exploit two complementary data sources. We first use detailed longitudinal information on debit and credit account transactions (providing a detailed measure of spending), balances, and limits from a financial aggregator in Iceland. We then test whether our results based on the financial aggregator data are supported by findings based on credit card data in a representative sample of U.S. credit card holders. Even though the U.S. data is not as detailed as the financial aggregator data, we believe that the replication of our findings in U.S. data ameliorates concerns regarding external validity of the results based on the aggregator data. In the following sections we will describe our data sources in detail.

4.1 Icelandic data: Financial Aggregator Data

The financial aggregator data we use is generated by Meniga, a financial aggregation software provider to European banks and financial institutions. Meniga's account aggregation platform allows bank customers to manage all their bank accounts and credit cards across multiple banks in one place by aggregating data from different financial institutions. We generate a panel of aggregated user-level data for different income and spending categories as well as account balances and credit limits for 2011 to 2017. We aggregate our data to the monthly level and restrict the analysis to individuals for which we have full records, defined by four requirements.

First, we restrict our sample to individuals for whom we see bank account balances and credit lines. Second, we restrict our sample to individuals for whom we observe income arrivals (this does not only include labor market income but also, e.g., unemployment benefits, pension payments, invalidity benefits, and student loans). The third requirement is that key demographic information about the user is available (age, sex,

11

and postal code). The final requirement is that the consumption of each user must be credible, which we ensure by requiring at least 5 food transactions in at least 23 months of a 24 months period.

The app also collects some demographic information such as age, gender, marital status, and postal code. Furthermore, we infer employment status from salary and unemployment benefit payments we see in the data. This data set has been proven useful in multiple studies, e.g., to analyze individual spending responses to income payments together with individual liquidity constraints (Olafsson and Pagel, 2018a), individual spending, savings, and consumer debt responses to retirement (Olafsson and Pagel, 2018b), and the drivers of individual attention to personal finances (Olafsson and Pagel, 2017).

Because our financial aggregator data is derived from actual transactions and account balances, it overcomes the accuracy, scope, and frequency limitations of the existing data sources of consumption, income, and financial standing. The data we use is exceptionally thorough and accurate with respect to capturing all income and spending because of three reasons: (1) the income and spending data are precategorized (and we have very few uncategorized transactions), (2) the app is marketed through banks and supplied for their customers (thus covering a fairly representative sample of the population), and (3) the data are basically free of one important shortcoming of all transaction-level data—the absence of cash transactions (in Iceland, consumers almost exclusively use electronic means of payment). Such detailed information on consumption is rare within this literature, which typically relies on proxies for consumption (e.g., car purchases), noisy survey measures of consumption, or imputed measures of consumption from yearly snapshots of wealth and income.

Description of sample

Table 2 displays summary statistics of employed and unemployed individuals. Furthermore, Figure 1 shows the evolution of income and unemployment benefits in the months around job loss while Figure 2 shows the distribution of the length of unemployment spells.

[Table 2 and Figures 1 and 2 about here]

The evolution of income and unemployment benefits shows that income increases slightly in the months leading up to job loss. This can be explained by the fact that unused holiday payments are paid out together with the last salary payment for individuals asked to leave their jobs. Upon unemployment there is a sharp drop in income which is quite stable and then increases. This can be explained by the fact that not all unemployed individuals claim their unemployment benefits from the very start of their unemployment spell (this does not mean that they forego their benefits, it only means they are paid out later).

As can be seen when looking at the distribution of the length of unemployment spells, the vast majority of unemployment spells are relatively short. The median length of an unemployment spell is 4 months while the mean length is 6.3 months. In terms of labor market regulations, Iceland is characterized by relatively flexible labor laws, more similar to the U.S. than continental Europe. Moreover, unemployment is low. In 2017 only 2.4% of individuals were unemployed. In comparison, the average unemployment in the Organization for Economic Co-operation and Development (OECD) countries in 2017 was 6%, 8% in the European Union and 4.5% in the U.S.

Historically, the Icelandic labor market has been characterized by a very low and stable rate of unemployment with unemployment generally fluctuating below 3%. Even during the financial crisis unemployment peaked at only around 8%. High levels of

economic growth in Iceland in the years after the 2008 financial crisis have helped reduce the level of unemployment down to its "normal" level. In that sense, we are not overly concerned that the crisis in Iceland matters for our findings. While the Icelandic financial crisis undoubtedly affected individuals, the country recovered very quickly after the crisis and experienced high economic growth and low unemployment during our entire sample period.[7] Furthermore, the fact that unemployment is and has been low in Iceland makes it unlikely that those without a job fear being unemployed for a long period of time, i.e., unemployment is arguably more of a transitory income shock in our setting than in countries where unemployment is higher.

Furthermore, Iceland is very similar to many other economies, including the U.S., when it comes to usage of high-interest unsecured consumer debt. Individuals hold on average approximately $2,000 in overdrafts, the main source of unsecured borrowing. Furthermore, if we condition on individuals having an overdraft, the average overdraft amount is approximately $6,000. In Iceland, individuals typically pay off their credit card in full and use overdrafts to roll-over debt (more details can be found in the next section). Nevertheless, individuals still enjoy substantial liquidity, i.e., they have liquid savings or borrowing capacity before they hit their liquidity constraints, $10,000 on average. In comparison, the Survey of Consumer Finances (SCF) shows that the average credit card debt for individuals rolling over is approximately $4,000 in the U.S. We thus believe that our results can be generalized to the U.S. and other European countries with relatively large consumer debt holdings, e.g., the UK, Spain, and Turkey.

---

[7]The OECD Economic Survey Iceland from June 2011 states that the economic contraction and rise in unemployment appear to have been stopped by late 2010 with growth under way in mid-2011. The Icelandic government was successfully able to raise $1 billion with a bond issue in June 2011, which indicates that international investors have given the government and the new banking system a clean bill of health. By mid-2012, Iceland was regarded as a recovery success story (Forelle, Charles (19 May 2012) Wall Street Journal.). According to OECD figures, the Icelandic economy grew by 7.2% in 2016, which was the second highest growth in the OECD in 2016.

Institutional background: borrowing and unemployment in Iceland

Individuals in Iceland use overdrafts as their main means of high-interest unsecured consumer debt. An overdraft occurs when withdrawals from a current account exceed the available balance. This means that the balance is negative and hence that the bank is providing credit to the account holder and interest is charged at the agreed rate. Virtually all current accounts in Iceland offer a pre-agreed overdraft facility, the size of which is based upon affordability and credit history. This overdraft facility can be used at any time without consulting the bank and can be maintained indefinitely (subject to ad hoc reviews). Although an overdraft facility may be authorized, technically the money is repayable on demand by the bank. In reality this is a rare occurrence as the overdrafts are profitable for the bank and expensive for the customer.

Wage earners in Iceland or self-employed individuals who lose their jobs may be entitled to unemployment benefits. More specifically, wage earners and self-employed individuals may be entitled to the basic unemployment benefits for the first half-month (10 working days) after they lose their job. After having been paid basic benefits for the first two weeks after the loss of their jobs, wage earners and self-employed individuals may be entitled to income-linked unemployment benefits for up to three months. The income-linked benefits of wage earners can be up to 70% of their average income during a six-month reference period beginning two months before the loss of employment.[8] The income-linked benefits of self-employed individuals can be up to 70% of their average income during the preceding income year in which the individual became unemployed. The amount is capped though, i.e., there is a certain maximum in the amount of monthly payments of unemployment benefits. Furthermore, after three months of unemployment, the income-linked benefits are canceled, and only basic benefits are paid thereafter. Unemployment benefits are paid for a maximum of thirty

---

[8]This reference period can never be shorter than four months.

months. Moreover, individuals receiving unemployment benefits who have children under the age of 18 to provide for may be entitled to an additional 4% of undiminished basic benefits for each child.[9]

After being in a job for six months, individuals are entitled to a three months notice of unemployment and can be entitled to a notice up to six months in advance (which is not the case for the majority of the population however). To include periods of time in which unemployment would have been unexpected at least for some of the sample, we begin four months prior to the beginning of unemployment for any event study illustrations.

Definitions of variables

Total discretionary spending - Spending is pre-classified into 15 categories and aggregated to generate a monthly panel. The spending categories are groceries, fuel, alcohol,[10] ready made food, home improvement, transportation, clothing and accessories, sports and activities, pharmacies, media, bookstores, thermal baths, toy stores, insurances, and various subcategories of recreation (e.g., cinemas, gaming, gambling etc.). Total spending is the sum of the spending in all these categories and excludes all recurring spending, e.g., rent and bills.

Necessary spending - Necessary spending is the sum of spending in grocery stores, gas stations and pharmacies.

Unnecessary spending - Unnecessary spending is the sum of spending in the alcohol, restaurants/take-outs, lottery, gambling, gaming, and cinema categories.

Cash - Cash is defined as the sum of checking and savings account balances, nor-

---

[9]The income-linked benefits are capped at approximately $3,800 while the basic benefits amount to approximately $2,400. Further details can be found here: https://vinnumalastofnun.is/en/unemployment-benefits/unemployment-benefit-amounts

[10]We can observe expenditures on alcohol that is not purchased in bars or restaurants because a state-owned company, the State Alcohol and Tobacco Company, has a monopoly on the sale of alcohol in Iceland.

malized by the average discretionary spending per day of individuals, i.e., we measure cash in consumption days.

Liquidity - Liquidity is defined as cash plus credit and overdraft limits minus credit card and overdraft balances, normalized by the average discretionary spending per day of individuals, i.e., we measure liquidity in consumption days.

Overdraft usage - We both look at whether individuals hold an overdraft in a given month, i.e., their checking account balance is negative at least once, and how many overdrawn checking accounts they have.

Late fees - Fees assessed for paying bills after their due date.

Income - We observe the following regular income categories: child support, benefits, child benefits, interest income, invalidity benefits, parental leave, pension income, housing benefits, rental benefits, rental income, salaries, student loans, and unemployment benefits. In addition, we observe the following irregular income categories: damages, grants, other income, insurance claims, investment transactions, reimbursements, tax rebates, and travel allowances.

4.2   U.S. Data: Consumer Credit Panel

For the U.S. replication, we use the Consumer Credit Panel (CCP) of the Federal Reserve Bank of New York containing detailed information on individual debt and credit (Lee and Van der Klaauw, 2010). The Consumer Credit Panel (CCP) is an anonymous longitudinal panel of individuals, comprising a 5% random sample of all individuals who have a credit report with Equifax for the period between 1999 and 2017.[11] The data is described in detail in Lee and Van der Klaauw (2010). We use a 0.01% sample for purposes of the current analysis, which includes information on approximately 250,000 randomly selected individuals each quarter. For our main specifications, we aggregate

---

[11]The quarterly sample starts in 1999 quarter 1 and ends in 2017 quarter 3.

data to the county level.

The CCP provides credit registry information on all debts monitored by one of the three main credit bureaus, in addition to public records (bankruptcies and deaths) and mobility (address changes) for all individuals that are visible to the credit registry (i.e., the very young and any others without reported debts are excluded). This panel data set allows us to track all aspects of individuals' financial liabilities, including their bankruptcies and foreclosures, mortgages, detailed delinquencies, various types of debts, the number of accounts, and balances. Information on location of residence is available at the census block level.

Table 3 provides summary statistics on the average change in revolving credit card debt as well as total debt balances and utilization ratios in the U.S. credit panel. It also reports the number of inquiries as well as individual risk scores, age, and income.

[Table 3 about here]

The main benefit of the U.S. data is that it provides an externally valid test of any of our findings based on the financial aggregator data. The CCP is a representative sample of the U.S. population and we can look at individuals' entire balance sheet responses because it links all borrowing and credit cards to each individual. Moreover, the sample is large and has sufficient statistical power to perform, e.g., quantile regressions. The main drawback is that we do not have information on income and employment status of the individuals in our sample, so we must restrict ourselves to examining borrowing responses to local unemployment shocks.

5 Methodology

5.1 Individual-level analysis using financial aggregator data

For the analysis using the financial aggregator data, we estimate the effect of unemployment by running the following regression

$$y_{i,t} = \beta_0 + \beta_1 Unemployment_{i,t} + \beta_2 X_{i,t} + \psi_t + \eta_i + \epsilon_{i,t} \tag{1}$$

where $y_{i,t}$ is the outcome under consideration—spending, savings, or use of consumer credit—of individual i at time t, $Unemployment_{i,t}$ is an indicator equal to 1 if i is unemployed at time t and equal to 0 otherwise. $X_{i,t}$ is a vector of controls, ψ_t are month-by-year fixed effects, and η_i is an individual fixed effect. The β coefficients thus measure by how much the individual outcome deviates when the individual is unemployed. The individual fixed effects control for all (un)observable individual characteristics. It is important to note that when we estimate the responses to unemployment in the months after losing a job and that we exclude observations in the last three months prior to the onset of unemployment. In turn, the interpretation of an unemployment estimate is relative to the individual outcome prior to receiving the unemployment notice.

Because economic models suggest that liquidity holdings are important for individual responses to transitory income shocks, we also modify our benchmark specification and allow for interaction effects between unemployment and liquidity. The specification is as follows:

$$y_{i,t} = \beta_0 + \beta_1 Unemployment_{i,t} + \beta_2 Unemployment_{i,t} * liquidity_{i,t-4}$$

$$+ \beta_3 liquidity_{i,t-4} + \psi_t + \eta_i + \epsilon_{i,t} \tag{2}$$

where $liquidity_{t-4}$ is the amount of liquidity, measured in number of average consump-

tion days, held by individual i four months prior to unemployment, to avoid problems of reverse causality. The reason for using liquidity four months before the onset of unemployment is that the vast majority of workers have a three months notice period.

5.1.1 Dynamic responses

How strongly spending and borrowing respond to a transitory income shock depends obviously on the time frame under consideration. The results above focus on the average effect within any month of unemployment. Of equal interest is how spending and borrowing respond to unemployment over time. We therefore also estimate impulse responses over the four months after losing a job, conditional on being unemployed for at least four months to make sure that the sample size for each of the coefficient estimates remains the same. We employ the following specification:

$$y_{i,t+k} = \beta_0 + \beta_{1,k}Unemployment_{i,t} + \psi_{t+k} + \eta_i + \epsilon_{i,t+k} \text{ for } k = -3, -2, ..., 3 \quad (3)$$

where the $\beta_{1,k}$s are the main coefficients of interest. Each $\beta_{1,k}$ represents the effect of unemployment on the outcome under investigation in month $t + k$. It is important to note that when we estimate the effect of a unemployment on the outcomes under investigation in the months after the loss of a job we include observations up to 3 months before they lost their job, where most individuals receive their notice of layoff, so as to capture any potential announcement effects. The cumulative effect is given by the sum of the $\beta_{1,k}$s.[12]

---

[12]The differences between the cumulative effects here and the estimated effects in our main specification can be explained by the following: for the impulse responses we make restrictions 1) we use the same individuals to estimate each of the $\beta_{1,k}$s, i.e., we restrict ourselves to individuals that we do observe unemployed for at least 3 months prior to the onset of their unemployment and 2) we only use individuals we observe unemployed for at least 4 consecutive months after that. In our main specification we do not make this restriction and we also exclude the 3 months prior to unemployment

5.2 Analysis using the U.S. credit panel

For the analysis using U.S. data, our main specifications regress dollar changes in credit outcomes aggregated at the county level on percentage changes in unemployment rates (results are similar using other measures of changes in employment conditions). While our main analysis is at the county-level, our additional analyses pursue individual-level variation.

As a source of exogenous variation in employment, we use a Bartik-style shift-share instrument for employment shocks. More specifically, the change in a county's employment is instrumented using the interaction of the pre-period industry mix of employment in that local labor market with the national change in industry employment (exclusive of the given county). National increases in demand in some sectors therefore result in exogenous changes in employment due to its industrial composition. Our exclusion restriction is that the pre-period industrial mix interacted with the national industry trend does not directly affect local credit card variables outside of its effect on employment.

More formally, we consider the following regression:

$$y_{c,t} = \beta \widehat{\Delta Unemployment}_{c,t} + \gamma X_{c,t} + \psi_t + \eta_c + \epsilon_{c,t} \tag{4}$$

when the credit outcomes studied are aggregated from individual-level outcomes by taking the mean in that county and time period. Before proceeding to quantile regression analysis using individual-level observations, we also confirm our county-level OLS findings using individual observations that allow for individual-level fixed-effects regressions, to confirm the estimates are largely unchanged:

because we do not want to confound the anticipation effect of unemployment and the actual effect.

$$y_{i,t} = \beta \Delta \widehat{Unemployment}_{c,t} + \gamma X_{i,t} + \psi_t + \eta_i + \epsilon_{i,t} \tag{5}$$

where $y_{i/c,t}$ is the credit outcome of individual i or county c at date t and $\eta_{i/c}$ is an individual or county fixed effect. The β coefficients thus measure by how much outcomes of individuals that live in counties that experience unemployment shocks deviate. Fixed effects control for all (un)observable individual or county characteristics and $X_{i/c,t}$ controls for time-varying characteristics such as individuals' (or counties' mean) credit scores. Furthermore, ψ_t are time fixed effects that capture any systemic changes/shocks across counties at each individual point in time.

To isolate a source of variation in $\Delta Unemployment_{c,t}$ we instrument it using a measure of predicted unemployment, defined in the following way:

$$\Delta PredictedUnemployment_{c,t} = \sum_i \left(\frac{Employment_{i,t}}{Employment_{i,t-1}} - 1 \right) EmploymentShare_{i,t-1,c}$$

where $\frac{Employment_{i,t}}{Employment_{i,t-1}} - 1$ is the change in the national employment of industry i from time $t-1$ to t and $EmploymentShare_{i,t,c}$ is the share of employment in industry i at time t in county c. As an employment outcome, for comparability to our Icelandic analysis, we focus on changes in unemployment rates (results are qualitatively similar when examining percentage changes in employment). We generate the above shocks using quarterly census data (QCEW).

The credit outcomes we consider are the change in credit card balances, the change in credit card limits, the sum of changes in all revolving debts (including home equity), the number of credit inquiries (from any lender or application), and the credit utilization ratio. The credit utilization ratio is calculated by dividing the outstanding balance on the category of revolving debt by the total appropriate credit limit. We report results

for both contemporaneous and delayed employment. For robustness, we report results where we control for delayed credit score and also where we only consider specific, shorter, time periods surrounding the financial crisis (2008 to 2014). Standard errors are clustered at the county level as the unemployment instrument is a county-level source of variation.

Analysis of conditional distributions using quantile regressions

Whereas the above regressions estimate a conditional mean of an outcome variable given certain values of predictor variables, a quantile regression aims at estimating any point on the conditional distribution, such as the conditional median or other quantiles. Recall that the τ-quantile of a distribution is the point on the support such that the probability of observing values at that point or below is $\tau\%$. Quantile regressions allow us to examine the data under the assumption that a particular quantile changes as a linear function of some variables x.

A quantile regression differs from an ordinary least squares regression in two key respects. First, the quantile regression minimizes the sum of absolute errors, rather than the sum of squared errors. Second, it puts differential weights on the errors depending on whether an error term is above or below a quantile. In a quantile regression of $y_{i,t}$ on $x_{i,t}$ the regression slope β_τ is chosen to minimize the quantile weighted absolute value of errors. More specifically, for a range of quantiles from 2 to 98, instead of $Q(\tau)$ being fixed at $Q(\tau) = a_\tau$, we assume that:

$$Q_{y_{i,t}}(\tau, x_{i,t}) = a_\tau + x'_{i,t}\beta_\tau \tag{6}$$

where $x_{i,t}$ includes any individual-level or time-varying controls in addition to county-level unemployment shocks, our variable of interest.

We use quantile regressions to examine heterogeneity in individual credit responses

to unemployment shocks. The quantile regressions allow us, for instance, to investigate whether any portion of the distribution responds as individuals would who were using credit cards for consumption smoothing. While the average borrowing response might be insensitive to unemployment shocks, there may be some borrowers responding strongly to changes in county-level unemployment rates by borrowing. To investigate this we can look at whether the upper quantiles of changes in credit card borrowing are (inversely) sensitive to changes in unemployment. Quantile regressions thus give us a more comprehensive analysis of the relationship between unemployment and borrowing in the U.S. data.

6   Results using financial aggregator data

Table 4 shows our estimates of the average effect of unemployment in Iceland, i.e., the β_1 coefficients of Equation 1 for the outcomes under consideration, both with and without individual fixed effects, and with and without interacting unemployment with liquidity holdings prior to the onset of unemployment. We focus on the first 4 months of unemployment to maximize sample size, and restrict our sample to individuals that are unemployed for at least 4 months.[13] The table shows the effect of unemployment on total discretionary spending as well as "necessary" spending (groceries, fuel, and pharmacies) and "unnecessary" spending (alcohol, restaurants, other activities, lottery tickets, gambling, gaming, bookstores, recreational sports, specialty stores, theatres, shows, and toys). It is important to note that we only consider discretionary spending

---

[13]The reason we restrict our analysis to individuals that are unemployed for at least 4 months is that we want to avoid including individuals that are unemployed voluntarily for a short period of time in our analysis. Individuals can leave their job and receive unemployment benefits for a couple of months before starting a new job. For individuals that would like to take some time off between starting a new job this might be an attractive option. However, these individuals are not those of interest to us. Individuals that want to take some time off from work are unlikely to do that for 4 months or longer and we therefore believe that by restricting our analysis to these individuals we exclude individuals that voluntarily leave their jobs.

and not consumption commitments, i.e., recurring spending, such as rent, mortgage payments, and utilities. Moreover, the table shows results for cash holdings (checking and savings account balances) as well as liquidity (checking and savings account balances plus credit limits minus credit card balances). We normalize cash holdings and liquidity by the daily average discretionary spending of individuals, i.e., we measure cash and liquidity in individual consumption days. Furthermore, we consider use of overdrafts, late fees, and credit lines. Credit lines are measured as distance to credit limits and normalized by average individual income. Table 5 shows results by income reduction terciles, Table 6 by initial liquidity, and Table 7 by whether or not an individuals holds an overdraft most of the time.

[Tables 4, 5, 6, and 7 about here]

We find that individuals decrease their spending considerably in response to unemployment by about 7% per month. Cash holdings are insignificant and average around zero while liquidity and credit lines are insignificant and also small. It appears that individuals make a conscious decision to cut down their spending and try to restrict themselves. When we break the results up by income reduction terciles we find that the reduction in spending is largest among individuals whose income is reduced the most. However, we do not find a significant increase in the probability of rolling over an overdraft among any of the groups. The coefficients for the probability of an overdraft is tightly estimated around zero and even in the 3rd income reduction tercile we can rule out an increase in the probability of holding an overdraft that is greater than 5%. Given that half of all individuals overdraft their checking account on average in any given month, we find that these overdrafts do not seem to be driven by unemployment. To make that more clear, we also split the sample according to whether or not individuals hold an overdraft most of the time. For both high-frequency and low-frequency users of overdrafts, we find similarly small and insignificant responses.

25

Whether or not we control for individual fixed effects has a large effect on the size of the coefficients and on the explanatory power, i.e., R^2. More specifically, the inclusion of individual fixed effects suppresses the regression coefficients while greatly increasing R^2. This underscores the importance of individual characteristics in the amount of borrowing the individual engages in, highlighting potential selection problems and the need to control for time-invariant characteristics (observable and unobservable). To the best of our knowledge, the analysis of individual-level data using fixed-effects regressions with transaction-level, high-frequency data has not been undertaken before in this literature and might explain why we conclude that borrowing is not used to smooth consumption in contrast to some existing papers (Browning and Crossley, 2009; Gruber, 1997; Keys, 2010; Sullivan, 2008).

We also do not see an effect of unemployment on the use of payday loans.[14] Furthermore, as can be seen in Figure 3, when investigating the use of payday loans more generally, we can see that a substantial fraction of borrowers are able to borrow money less expensively and spend their loans on unnecessary items. The figure plots the distribution of individual liquidity, i.e., space that individuals have until they reach their credit limits, net the amount of the payday loan. For 65% of individuals, this amount is negative, but 35% of individuals could have tapped their existing credit instead of borrowing using a payday loan. Furthermore, Table 8 analyses the consumption categories on days in which individuals take out a payday loan versus other days. It can be seen that individuals do not only spend on necessary goods and services on payday loan days but seem to increase spending on unnecessary goods and services even more. This supports that high-interest unsecured consumer loans are in most cases not used in response to rainy days and suggests that self-control or poor information are proximate causes of payday borrowing, rather than liquidity constraints.

---

[14]Payday loans in Iceland are not contingent on income from paychecks and unemployment benefits provide predictable and regular income payments.

[Figure 3 and Table 8 about here]

In Figure 4 we show the impulse response of unemployment on spending. Clearly, individuals cut their consumption considerably at the onset of unemployment and then increase it gradually.

[Figure 4 about here]

In Figure 5 we look at the impulse response of the probability of holding an overdraft to unemployment controlling for individual and month-by-year fixed effects. Estimated values are with respect to 4 months prior to job loss (period -4) since the standard notice period is 3 months. We do not find significant results as can be seen in Figure 5 and all estimates and standard errors are small.

[Figure 5 about here]

We thus document an obvious discrepancy between our theoretical and empirical results. In the event of an income shock calibrated to the Icelandic unemployment replacement rate, the hyperbolic agents in the model, calibrated to match the real-world borrowing on credit cards that we see, increase their amount borrowed by 319%, the probability to borrow by 31%, and decrease their spending by 7%. While the spending responses matches the data quite well, the borrowing response is completely off. Clearly, in the model, the reason to borrow is to smooth consumption in response to transitory income shocks, however, we do not find such behavior in the data.

6.1 Robustness Checks

In this section we examine potential explanations for the spending responses that we observe during unemployment spells. Among the most plausible explanations for the difference between the predictions of the theoretical models and the empirical evidence

are binding liquidity constraints, changes in beliefs about permanent income, and shifts from market goods to home production. In the following subsections we will subject our findings to a number of robustness checks that are designed to assess the empirical relevance of each of these potential explanations for our findings.

6.1.1 Binding liquidity constraints

As can be seen in Table 4, interacting unemployment with liquidity does not change our main findings. Liquidity holdings do not appear to explain how individual spending and consumer debt respond to unemployment. Furthermore, as can be seen in Table 2, both employed and unemployed individuals have substantial liquidity or borrowing capacity, i.e., cash holdings or space until they hit their credit and overdraft limits. Unemployed individuals have on average more than \$8,000 in funds left which translates into more than 150 days or five months of discretionary spending. They are therefore not obviously liquidity constrained on average.

It is interesting to compare these regression results to the results in Table 6 where we show results for individuals who have above and below median liquidity. The results in Table 6 show that the effect of unemployment on spending is much more pronounced among individuals with low liquidity. Liquidity measures actual borrowing capacity and we see a significant negative change for low-liquidity individuals but this is almost entirely driven by reductions in cash holdings rather than decreases in credit lines (which is insignificant and small). Most importantly, we do not see any significant effect on the likelihood to borrow and the zero effect is tightly estimated.

It is also important to note here that sorting based on an endogenous variable (liquidity or income) and running separate regressions for each group is not inconsistent with liquidity playing an important role. However, such sorting does not provide a strong test for the importance of liquidity in determining how spending and borrowing

respond to an adverse transitory income shock such as unemployment in our setting. After all, individuals with high or low income or liquidity are very different on an uncountable number of dimensions. Interacting unemployment with liquidity holdings prior to job loss provides a more powerful within-individual test and suggests that limited liquidity is not the reason for a lack of borrowing in response to unemployment.

6.1.2 Changes in beliefs about permanent income

The lack of a borrowing response could be explained if individuals were hit by permanent income shocks. However, when we compare the incomes of individuals before and after their job loss, we find that their income is not permanently lower after they lose their jobs. This can be seen in Figure 6 that plots the evolution of labor income prior to and after the onset of unemployment, independent of the duration of the unemployment spell. The share of the unemployed individuals thus decreases as we move further away from the onset of unemployment and the average labor income increases. Around 11 months after the onset of unemployment there is no statistically significant difference in the average income of individuals who at some point lose their job from their average income prior to the onset of unemployment. This shows that unemployment is indeed a transitory income shock in the setting of our paper. As discussed earlier, throughout the sample period, the Icelandic economy was growing substantially and unemployment was consistently low throughout so that unemployment shocks are transitory income shocks. As mentioned earlier, unused holidays are paid out with the last salary payments for individuals who are asked to leave their jobs. This explains why we see an income increase in the months prior to the start of an unemployment spell.

[Figure 6 about here]

It could be the case that individuals are uncertain about whether the unemployment shock is permanent or transitory, or could even hold systematically biased beliefs

about the severity of the shock, and therefore be reluctant to borrow more. Rozsypal and Schlafmann (2017) show that there is over-persistence bias in individual income expectations although Druedahl and Jørgensen (2018) show that people seem to be able to distinguish between permanent and transitory income shocks. Furthermore, there is a study by Spinnewijn (2015) on individual beliefs about the duration of unemployment showing that people underestimate the length of unemployment spells. The effects of misguided beliefs about shock persistence is outlined in a general-equilibrium model in Kozlowski et al. (2016). Importantly though, even in models such as the one in Rozsypal and Schlafmann (2017) any agent with a concave utility function would borrow more in the event of adverse transitory income shocks which we cannot find in the data. Furthermore, as discussed, we argue that the Icelandic situation makes it unlikely that people think their income is permanently affected. Moreover, individuals hold high-interest consumer debt, they must have build it up somehow but unemployment does not appear to be a reason even though unemployment probably constitute the largest transitory income shocks individuals face.

6.1.3 Substitution from market goods towards home production and non-separabilities between consumption and leisure

Theory predicts that if preferences over consumption and leisure are non-separable then individuals will smooth their marginal utility from consumption and adjustment in leisure can therefore lead to changes in consumption. Furthermore, having more time on their hands implies that the opportunity cost of home production is reduced so the unemployed are likely to substitute market goods with home produced goods, causing a decline in spending. Such time allocation response is plausible but is often difficult to verify empirically due to data limitations. Unemployed workers may also be able to forgo work-related expenses like commuting. However, at the same time many workers

receive either subsidized or free meals during working hours and are able to combine their work commute with, e.g., bringing children to school of daycare.[15] Other research (see, e.g., Gruber, 1997; Guler and Taskin, 2013) that has focused on this question has found significant declines in actual expenditures among the unemployed but smaller declines in proxies for consumption or utility. However, because there are arguments for both increases (e.g, no more free meals) and decreases (less commuting costs) in expenditure in relation to no longer attending work it is not clear whether the findings of previous studies that are conducted in a particular setting can necessarily be applied to other settings. This is therefore an empirical question that needs to be investigated in each setting.

We use the richness of our data to look for direct evidence of changes in home production and leisure spending. We re-estimate our main specification for different spending categories and the results are shown in Figure 7. If unemployed individuals are substituting from market goods towards more home production, this would be evident through relatively greater decreases in spending on items such as restaurants and relatively smaller decreases or even increases in spending in grocery stores for instance. However, as can be seen in 7, the reduction in restaurant and grocery store spending is remarkably similar. Furthermore, other expenditures that serve as proxies for work related expenses, e.g., fuel spending, is reduced by about as much as proxies for leisure expenses, e.g., recreation. These finding suggest that substitution from market goods to home production as an explanation for drop in spending upon job loss does not seem to be empirically relevant in the setting of this study.

One potential explanation for a drop in spending during a transitory income decline

---

[15]Daycare in Iceland is highly subsidized and is provided for children from the age of 6 months. However, getting a spot often requires some waiting and if parents take their children out of the daycare facility during unemployment spells they can in general not get the same slot again once they return to work. Taking children out of daycare in order to reduce expenses during periods of unemployment is therefore highly unlikely. Children start elementary school at the age of 6 and schools are free.

is that individuals simply consume previously-purchased nonperishables while their spending on perishables remains the same. We can test for this directly by comparing spending in consumption categories which can be labeled as durables and nondurables. Figure 7 shows that we we find a statistically significant reduction in all main consumption categories except for alcohol and that the response of some perishable spending categories, e.g, ready-made-food spending, and some nonperishable spending categories, e.g., home production, are similar. This suggests that the perishability of goods spent on cannot explain our findings.

To summarize, our findings based on the financial aggregator data support that individuals smooth their consumer credit usage during adverse transitory income shocks while they let consumption adjust. But even if individuals would be able to make up for their reduction in salary income by home production, the question remains: why do we observe such large consumer debt positions? If large transitory income shocks, such as unemployment, are not the reason as our models predict, then what are the reasons?

7 Results using the U.S. credit panel

Figure 8 shows the mean changes in credit card balances by quantiles of Bartik unemployment variation. We see that the largest average changes in total revolving credit card balance (of around $50 to $100) are in the lowest deciles of unemployment shocks (i.e. positive employment shocks). Overall, better county employment outcomes appear to be correlated with more, rather than less, borrowing. Figure 8 also breaks down the estimation sample by individuals with or without credit card borrowing slack, taking a first step at distinguishing demand from supply. The more constrained sample has a borrowing response that is only half of the less constrained sample. However, even unconstrained individuals with an unfavorable employment shock do not appear to in-

32

crease their borrowing. Thus, more constrained individuals decrease their borrowing when negative employment shocks occur. We do not observe a positive relationship between unemployment and borrowing in these figures.

[Figure 8 about here]

Table 9 reports our main regression results based on the CCP, with changes in revolving credit card balances as the outcome variable, and focusing on short horizons of the same period and one quarter from the shock. We first run our regressions with outcomes aggregated to the county level. The first stage F-statistics do not indicate weak identification (F-statistic > 30).

We estimate small and mostly statistically insignificant average borrowing responses to unemployment. The range in estimates varies from a $28 to $115 increase in credit card balances for a one standard deviation (approximately 1%) increase in the total unemployment rate. Looking at the mean borrowing response to employment shocks tends to reject consumption smoothing as a consistent driver of unsecured borrowing. Analysis using alternative measures of employment (% change in employed, change in logs) provide similar statistically insignificant results.

While we have already controlled for what is likely to be the main determinant of supply-side constraints over this period (lagged credit scores), we also find similar results when only looking at changes in credit card balances amongst those individuals with slack in their utilization ratio as can be seen in Table 10. In addition, when interacting employment shocks with lagged utilization ratios in Table 10, we find a positive coefficient estimate that (under some reasonable conditions and if it were statistically significant) would be inconsistent with increases in credit card borrowing by individuals with low utilization ratios and far from their borrowing limits. This further supports our argument that supply-side constraints do not seem to be driving results. We also

find the size of a borrowing response is negatively related to baseline income, i.e., lower income individuals tend to respond to unemployment shocks with more positive changes in borrowing, which would also appear to argue against supply-side constraints. The lack of a robustly positive relationship between borrowing and unemployment in the U.S. data does not appear to be driven by limited access to credit. Later in this section, we will present additional evidence from changes in credit limits and new inquiries (applications for new credit) that is also inconsistent with an access-to-credit story.

[Tables 9 and 10 about here]

We next rerun our main regression with changes in credit card balances at longer horizons. Standard errors are clustered at the county level. The estimates are not majorly affected as can be seen in Table 11. Many estimated coefficients are approaching statistical precision with relatively tightly estimated standard errors, indicating 95% confidence intervals of +/- $100 in credit card balances for one standard deviation (approximately 1%) change in unemployment rate. Most point estimates fall inside of this range and are statistically insignificant.

[Table 11 about here]

Our results are thus different than the ones in Keys et al. (2017), who exploit a similar source of instrumental variation in employment. Based on efforts to replicate their findings as closely as possible, these differences can be reconciled by two main differences in the analyses. First, our results are based on individual-level observations while theirs is based on card-level observations aggregated up to the county-level and weighted by the number of cards in a county. If individuals with different number of cards behave differently (which seems plausible), a different relationship should be reflected in different estimates from aggregating individual-level rather than card-level

data. Secondly, Keys et al. (2017) focus on the cross-sectional variation of the Bartik employment shock in the first quarter of 2008, examining various longer horizon outcomes in response to that shock, while we focus on shorter-run responses to employment shocks, pursuing a panel analysis of shocks over the period 2000 to 2016.[16]

Table 12 collapses the results of various additional regressions examining additional credit outcomes. As can be seen there, it does not appear that the supply of credit responds to the cross section of Bartik shocks, as we estimate insignificant coefficients close to zero on changes in total credit card limits. Again, the coefficients appear tightly estimated with larger estimates when examining shocks arising in the previous period. Two more credit outcomes speak to the demand versus supply of credit: the credit utilization ratio and new inquiries. For credit utilization we again estimate an economically insignificant relationship, with coefficients which we would describe as precise zeros (for utilisation at the end of the same quarter as the shock, coefficients of less than 0.3%). For inquiries, we estimate small (while sometimes positive and sometimes negative) coefficients for the whole sample period (and the crisis period from 2008 to 2014), with absolute magnitudes less than 0.01, as shown in Table 12. Again, it does not appear as if individuals are being denied access to credit from existing lenders, at least not as captured by applications for new lines of credit.

The picture of little average changes in borrowing is similar when we turn to look at total revolving credit, which includes instruments such as home equity loans. We estimate again economically insignificant coefficients for changes in unemployment as instrumented by Bartik shocks. The coefficients are all small (less than $15 for a one

---

[16]If we discard these two differences we can reproduce similarly, economically and statistically significant point estimates using a tradeline data set recently available for the CCP sample. This replication does not exclude other potential factors, such as a different sample. The Consumer Financial Protection Bureau (CFPB)-derived sample of credit card tradeline data is a much larger sample of slightly fewer issuers, and has approximately 90% similar issuer coverage to start with for the period 2008-2014. Keys et al. (2017) eliminate cards from any issuers not observed over the entire period to generate a balanced sample for their analysis, which could lead to larger differences between samples.

percentage point increase in unemployment rate), with standard errors of approximately the same magnitude. Finally, looking at delinquencies or non-current balances, it does not appear as if the source of variation in unemployment we use is statistically related to falling behind on payments. The confidence intervals are wider (95% confidence intervals of $+/-$ \$200 for a one percentage point increase in unemployment rate) and the signs of the point estimates are inconsistent when estimating the relationship of delinquency in the same or the next quarter from the unemployment shock.

[Table 12 about here]

Finally, we examine the conditional distribution of borrowing at the individual level with Bartik-unemployment shocks as the forcing variable. What would we expect to see in the data if individuals use credit cards primarily to smooth consumption in response to industry-predicted employment shocks? We would expect to see at least the upper tail of the distribution in individual borrowing respond positively and strongly. Table 13 therefore reports estimation results based on quantile regressions that examine whether the results vary along the conditional distribution. Across the distribution, we estimate either statistically insignificant borrowing responses or statistically significant, but "wrongly" signed (to a smoothing motivation) responses of credit card borrowing to unemployment. The upper end of the conditional distribution of changes in credit card borrowing, if anything, appears to be negatively related to employment conditions. Across the distribution, the only large or statistically significant point estimates we see are negative to unemployment. Focusing on the top half of the conditional distribution, the 75th quantile is estimated with statistically significant precision and indicates a less than \$1 increase in response to one standard deviation in the Bartik shock (these shocks are approximately mean 0, standard deviation 2.5%).[17]

---

[17]Out of practical necessity, currently the quantile regressions are estimated in reduced form, without an instrumented second stage, and with non-robust/unclustered standard errors, which we expect to be

The largest increases in borrowing (the upper quantiles) appear to occur regardless of the size of unemployment shock. In a world where credit card borrowing is primarily for consumption smoothing, we would expect to see the upper tail of the distribution meaningfully and positively respond to an increase in unemployment. The fact that we do not suggests that the largest changes in credit card borrowing are for non-consumption smoothing purposes. Instead of a positive relationship to unemployment, we find consistent negative estimates across the distribution. We thus conclude that the primary usage of credit cards is not in response to unemployment.

[Table 13 about here]

To verify the robustness of our results, we conduct two additional checks (results in Appendix Tables A.1 and A.2.). First, we rerun our regressions examining changes in borrowing weighting our regressions with the number of people in a county. Second, we rerun our regressions at the individual level with individual fixed effects (see Equation 5) . When using analytical weights by the population in a county, the point estimates tend to move closer to zero and are now statistically significant, with a percentage point increase in the total unemployment rate associated with a $30 average increase in credit card balances. Controlling for individual and time fixed effects as well as lagged risk scores and age, we estimate some statistically significant, but all economically small, coefficients of $20-$30 increases in credit card borrowing for a one percentage change in the county unemployment rate as instrumented for with Bartik shocks, as can be seen in Table A.2. To interpret the magnitudes of these coefficients, note that the standard deviation in the unemployment rate is less than 1%. The estimates also do not greatly vary depending on the choice of time period (the entire sample available, versus 2008 to 2014 only).

---

non-conservative to statistical significance. Their intent is to illustrate the shape and size of conditional distribution to underlying instrumental variation.

8 Conclusion

Economists believe that high-interest, unsecured, short-term borrowing, for instance via credit cards and overdrafts, can help individuals to smooth consumption in the event of transitory income shocks (Browning and Crossley, 2009; Gruber, 1997; Keys, 2010; Sullivan, 2008). After analyzing two data sets, however, we conclude that individuals do not appear to use such credit to smooth consumption through transitory income shocks. In contrast, it appears as if individuals smooth their debt balances rather than their consumption.

We document this lack of borrowing in response to unemployment directly using a longitudinal data set containing detailed information on consumption, income, and account balances as well as limits from a financial aggregator platform in Iceland. We then turn to U.S. credit card data to replicate the lack of a borrowing response to unemployment shocks using a Bartik (1991) style methodology.

By comparing our empirical results to the theoretical predictions of a state-of-the-art model to explain the amount of borrowing we see in the data, we document an obvious discrepancy: in the model, agents increase their amount borrowed by 101% and decrease their spending by 9%. While the spending responses matches the data quite well, the borrowing response is completely off. Clearly, in the model, the reason to borrow is to smooth consumption in response to transitory income shocks, however, we do not find such behavior in the data.

Our findings are difficult to reconcile with theories of consumption smoothing that predict that credit demand should be countercyclical and lean against changes in credit supply. On the contrary, our findings show that consumers appear to smooth their unsecured debt burdens rather than their consumption responses. Such behavior could lead to greater consumption volatility than observed otherwise.

Figures and tables

Table 1: The effect of low income on borrowing and consumption in the model of Laibson et al. (2017)

	(1) Log of total borrowing	(2) Indicator for borrowing	(3) Log of total spending
Hyperbolic-discounting agent:			
income below 67th percentile	3.1926***	0.3126***	-0.0673***
	(0.0061)	(0.0006)	(0.0019)
Standard agent:			
income below 67th percentile	0.0213***	0.0026***	-0.0301***
	(0.0005)	(0.0001)	(0.0009)
#obs	71,000	71,000	71,000
Age fixed effects	✓	✓	✓

This table shows the estimated effect of an income realization below the 67th percentile in the simulated data of the model in Laibson et al. (2017), featuring an illiquid asset, credit card borrowing, liquidity constraints, and stochastic labor income. The hyperbolic discounting agent borrows on average 35% of the time and the standard agent 0.15% of the time. Standard errors are within parentheses. Each entry is a separate regression.

Table 2: Summary statistics

	employed		unemployed

* $p<0.1$, ** $p<0.05$, *** $p<0.01$ This table shows the estimated effect of being unemployed. Standard errors are clustered at the individual level and are within parentheses. Each entry is a separate regression. Cash holdings are checking and savings account balances and liquidity is checking and savings account balances plus overdraft limits and credit limits minus credit card balances. Cash and liquidity are measured in days of average spending by individuals.
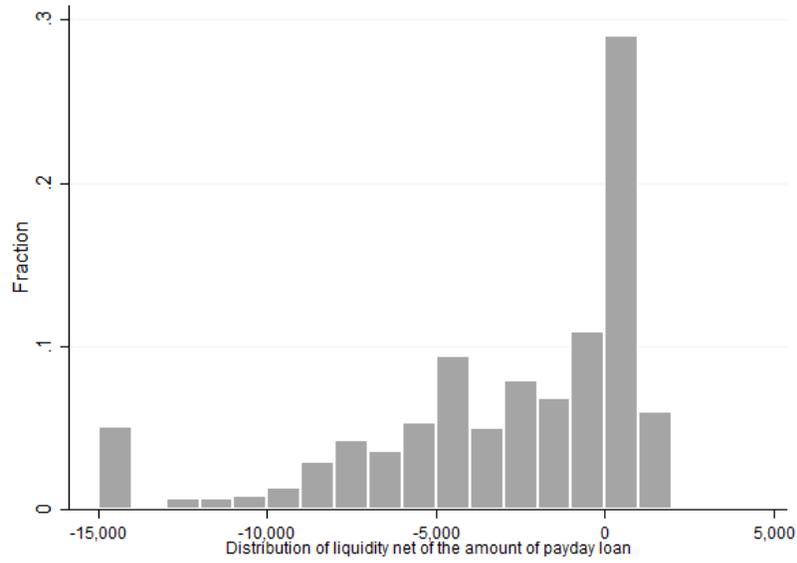

Figure 3: Distribution of liquidity net of the amount of payday loan

Table 8: Daily expenditures by payday loan users

	Days receiving loans		Days without loans		difference
	Mean	St. Dev.	Mean	St. Dev.	
Total expenditures	62.3	75.7	29.3	99.5	113%
Groceries	23.2	40.6	10.6	30.3	120%
Fuel	13.0	30.1	5.4	20.6	140%
Alcohol	3.8	14.0	1.4	9.8	162%
Ready-made-food	12.3	24.2	5.1	16.5	139%
Home improvement	2.6	17.3	2.0	27.8	28%
Transportation	2.4	17.6	1.4	73.2	67%
Clothing and accessories	2.2	18.5	1.4	17.2	55%
Sports and activities	1.2	12.0	0.8	12.9	46%
Pharmacies	1.5	8.1	0.9	7.2	61%

Note: All numbers are in US dollars.

Figure 4: The impulse response of expenditure to unemployment

Notes: Regression coefficients and 95% confidence intervals for each month before and after unemployment with individual and month-by-year fixed effects, estimated with respect to all months prior to 3 months before start of job loss.

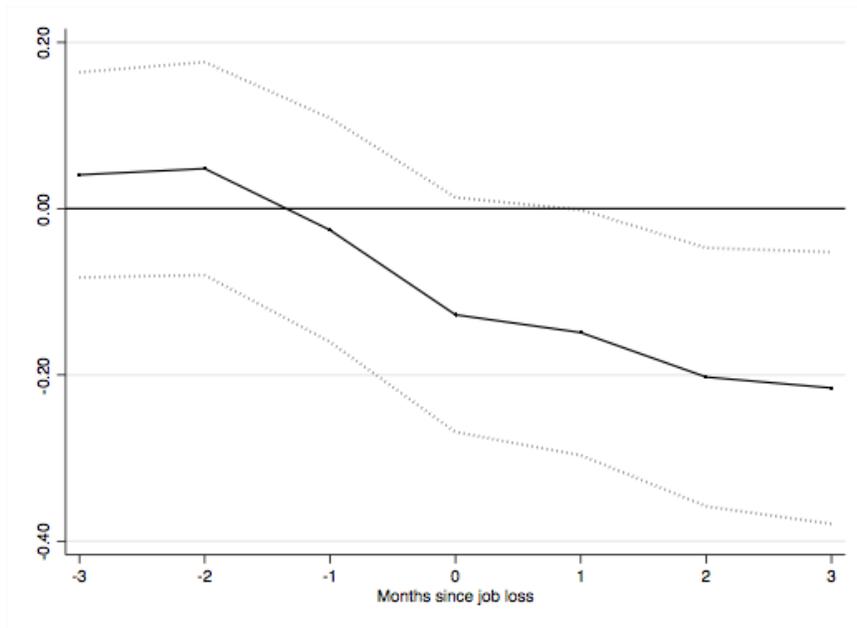

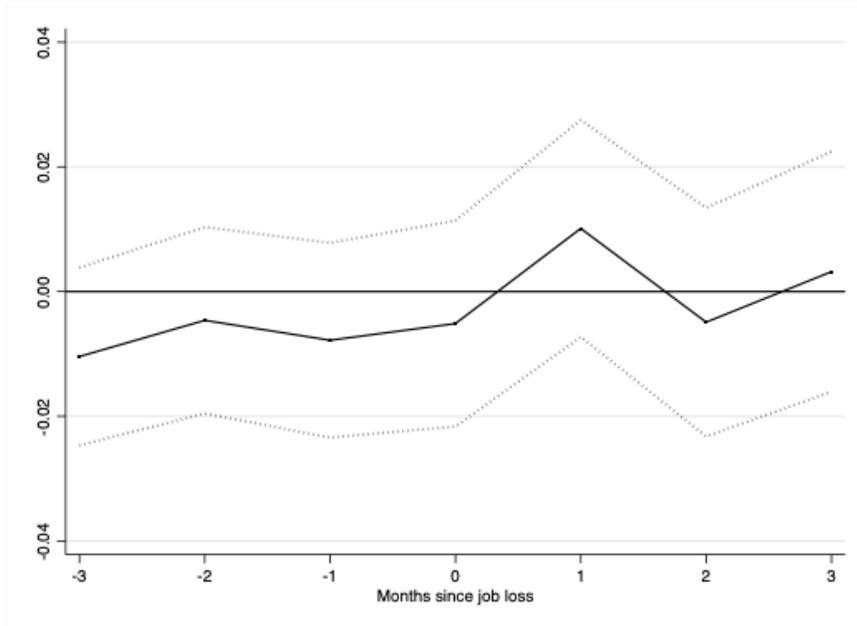

Figure 5: The impulse response of overdraft usage to unemployment

Notes: Regression coefficients and 95% confidence intervals for each month before and after unemployment with individual and month-by-year fixed effects, estimated with respect to all months prior to 3 months before start of job loss.
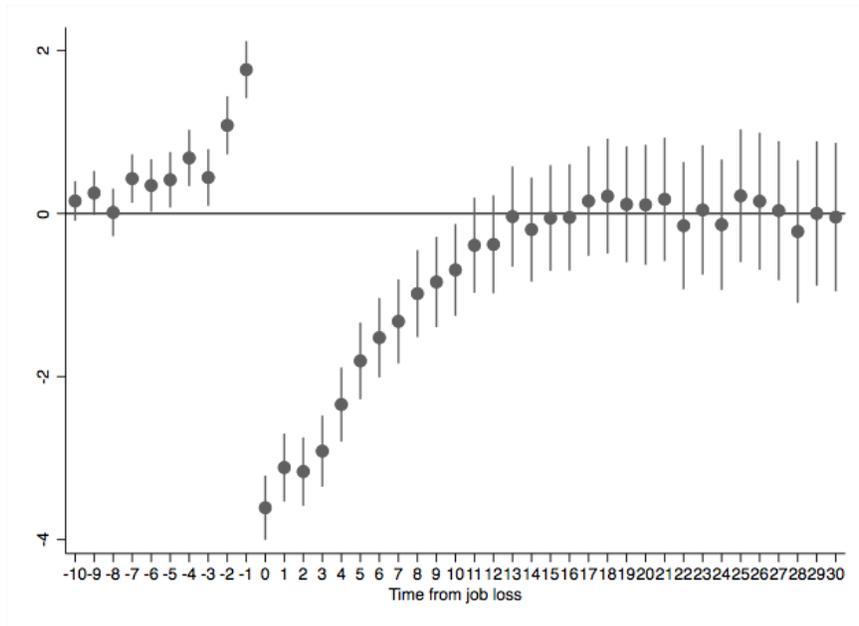

Figure 6: Labor income prior to and after onset of unemployment
Notes: Labor income is calculated in constant prices and we control for individual and month-by-year fixed effects.
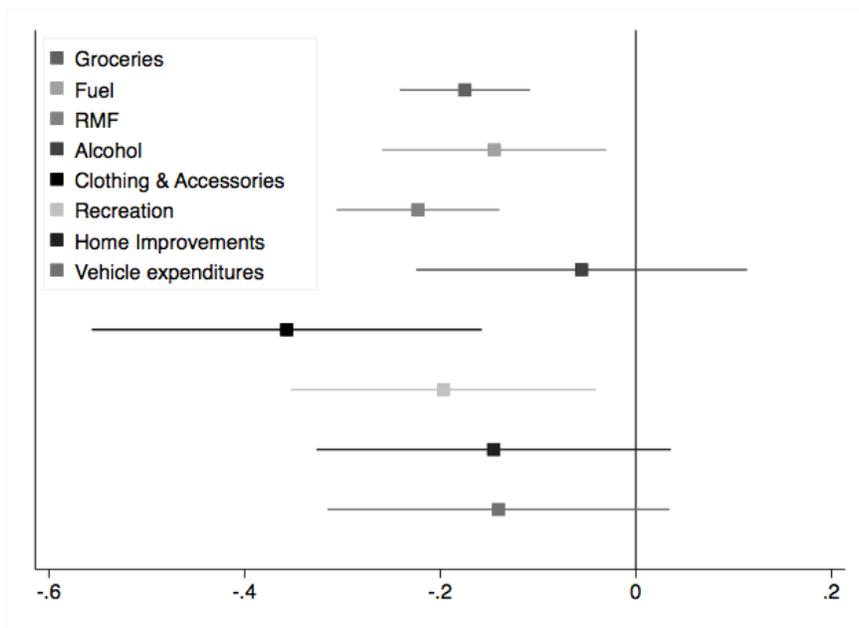

Figure 7: Spending responses by consumption category
Notes: We control for individual and month-by-year fixed effects.
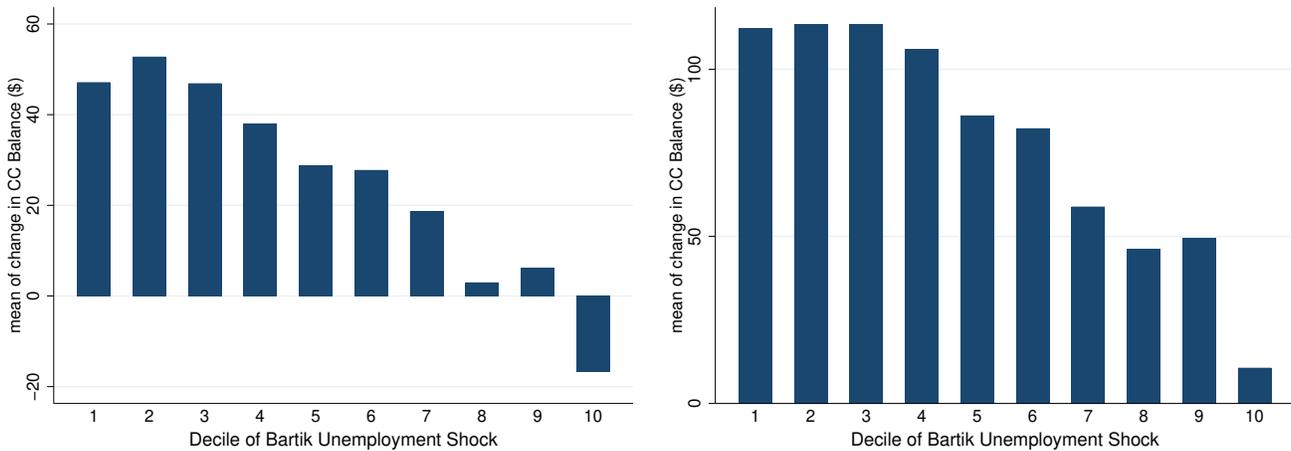

Figure 8: Mean changes in credit card balances by unemployment shock decile in U.S. data.
Notes: The observations underlying this figure are at the individual-quarter level, from a 0.1% representative sample of U.S. credit reporting from the FRBNY/Equifax CCP. Mean changes in credit card balances are arranged by decile of county-level Bartik unemployment shock experienced (decile 10 represents the largest unemployment shock). The figure on the left is generated for the whole sample, while the figure on the right is only for individuals with credit card "slack", where slack is defined as having a utilization ratio on their credit cards in the previous quarter of less than 0.9.

R^2	0.025	0.058	0.002	0.064

[a] * p<0.1, ** p<0.05, *** p<0.01   [b] Notes: This table presents the second stage of 2SLS estimates as detailed in section 3.2, with county-quarter observations of the mean change in credit card balances from the FRBNY/Equifax CCP. "Unemployment" refers to total unemployment rate (in %) at the county-level. "risk score" is an Equifax credit score similar to FICO in construction and scale. The change in the (lagged) county unemployment rate is instrumented for with the Bartik employment shock at the county level. Controls for county and time (month-by-year) fixed effects as well as age and lagged risk scores are included. Standard errors are clustered at the county level and are within parentheses.

Table 10:   Change in county-level credit card balances by ex-ante borrowing constraints

	Δ credit card balance		Δ credit card balance (if slack in utilization ratio)
