An Equilibrium Model of Institutional Demand and Asset Prices∗

Ralph S.J. Koijen† Motohiro Yogo‡

Abstract

We develop an asset pricing model with rich heterogeneity in asset demand across investors, designed to match institutional holdings. A portfolio-choice model implies a characteristics-based model of asset demand when returns have a factor structure and expected returns and factor loadings depend only on the assets’ own characteristics. We propose an instrumental variables estimator for the asset demand system to address the endogeneity of institutional demand and asset prices. Using U.S. stock market data, we illustrate how the model could be used to understand the role of institutions in asset market movements, volatility, and predictability.

I. Introduction

Modern asset pricing models are built on asset demand, derived from optimal portfolio choice, and market clearing. However, the common practice is to ignore institutional or household holdings data in estimating these models, even though these data are direct observations of asset demand. The predominant methodology for estimating asset pricing models, based on simplifying assumptions, uses portfolio returns alone or the joint moments of returns and aggregate or individual consumption. Although institutional holdings data have been used in the empirical asset pricing literature, an equilibrium model that simultaneously matches asset demand and imposes market clearing does not exist.

We develop an asset pricing model from the optimal portfolio choice of investors that have heterogeneous beliefs and face short-sale constraints. The investor’s first-order condition is a constrained Euler equation that relates the intertemporal marginal rate of substitution to asset returns (Lucas 1978). An approximate solution to the portfolio-choice problem is the mean-variance portfolio (Markowitz 1952), where the optimal portfolio varies across investors because of heterogeneous beliefs. Following the empirical asset pricing literature (e.g., Fama and French 1993), we assume that returns have a factor structure and that expected returns and factor loadings depend only on the assets’ own characteristics. Under this assumption, we show that the mean-variance portfolio simplifies to a characteristics-based model in which asset demand depends on observed characteristics (e.g., market equity, book equity, profitability, investment, dividends, and market beta) and latent demand (i.e., characteristics unobserved to the econometrician). We estimate the mean-variance portfolio on stock market data to show the empirical relevance of the assumptions under which the mean-variance portfolio simplifies to the characteristics-based model.

The characteristics-based model allows for rich heterogeneity in asset demand across investors and matches institutional holdings, including zero holdings and index strategies. We allow the coefficients on characteristics to vary across investors so that the aggregate demand elasticity varies across assets that are held by different sets of investors. The characteristics-based model allows for more flexible cross-elasticities across assets than traditional models that make simplifying assumptions that imply homogeneous asset demand across investors (Tobin 1958). In that sense, the characteristics-based model resembles an older literature on macroeconomic models of asset demand (Brainard and Tobin 1968; Tobin 1969) and differentiated product demand systems (Lancaster 1966; Rosen 1974), but the new contribution is to derive asset demand from optimal portfolio choice in the tradition of modern asset pricing theory. We show that the equilibrium price vector is uniquely determined by market clearing across institutional investors and households, under a simple condition that demand...
is downward sloping for all investors.

Although our contribution is primarily methodological, we illustrate our approach using U.S. stock market and institutional holdings data, based on Securities and Exchange Commission Form 13F. The 13F data contain quarterly stock holdings of institutions that manage more than $100 million since 1980. The types of 13F institutions are banks, insurance companies, investment advisors (including hedge funds), mutual funds, pension funds, and other 13F institutions (i.e., endowments, foundations, and nonfinancial corporations). These institutions collectively manage 63 percent of the U.S. stock market with the remaining 37 percent attributed to direct household holdings and non-13F institutions.

To identify the asset demand system, we start with the traditional assumption in asset pricing that shares outstanding and characteristics other than price are exogenous, determined by an exogenous endowment process. To relax the traditional assumption that investors are atomistic and that demand shocks are uncorrelated across investors, we propose an instrumental variables estimator to address the endogeneity of latent demand and asset prices. Our identifying strategy is motivated by an observation that institutions hold a small set of stocks and that the set of stocks that they have held in the recent past (e.g., over the past eight quarters) hardly changes over time. This observation is consistent with the fact that many institutions are subject to an investment mandate (i.e., a predetermined rule exogenous to current demand shocks) that limits their investment universe (i.e., the set of stocks that they are allowed to hold). An asset that is included in the investment universe of more investors, especially if those investors are large, has a larger exogenous component of demand. With downward-sloping demand, a larger exogenous component of demand generates higher prices that are unrelated to latent demand. A potential threat to identification is that we cannot measure the investment universe perfectly, but future research could improve upon our framework through new data or methodology that leads to better measurement of the investment universe.

After estimating the asset demand system, we illustrate our approach to asset pricing through four applications. First, we estimate the price impact of demand shocks for all institutions and stocks, which arises from imperfectly elastic aggregate demand. We find that price impact for the average institution has decreased from 1980 to 2014, especially for the least liquid stocks at the 90th percentile of the distribution. This means that the cross-sectional distribution of price impact has significantly compressed over this period. For example, the price impact for the average investment advisor with a 10 percent demand shock on the least liquid stocks has decreased from 0.87 percent in 1980 to 0.25 percent in 2014.

Second, we use the characteristics-based model to decompose the cross-sectional variance
of stock returns into supply- and demand-side effects. The supply-side effects are changes in shares outstanding, changes in characteristics, and the dividend yield. These three effects together explain only 8 percent of the cross-sectional variance of stock returns. The demand-side effects are changes in assets under management, the coefficients on characteristics, and latent demand. Changes in assets under management explain 29 percent, but changes in latent demand are even more important, explaining 59 percent of the cross-sectional variance of stock returns. Thus, stock returns are mostly explained by demand shocks that are unrelated to changes in observed characteristics (i.e., “excess volatility” according to Shiller (1981)). These moments establish a new set of targets for a growing literature on asset pricing models with institutional investors, just as the variance decomposition of Campbell (1991) has been a useful guide for consumption-based asset pricing.

Third, we use a similar variance decomposition to examine whether larger institutions explain a disproportionate share of the stock market volatility in 2008. We find that the largest 25 institutions, which manage about a third of the stock market, explain only 6 percent of the cross-sectional variance of stock returns. Smaller institutions, which also manage about a third of the stock market, explain 42 percent of the cross-sectional variance of stock returns. Direct household holdings and non-13F institutions, which account for the remaining third of the stock market, explain 48 percent of the cross-sectional variance of stock returns. The largest institutions explain a relatively small share of stock market volatility because they tend to be diversified buy-and-hold investors that hold more liquid stocks with smaller price impact.

Fourth, we use the characteristics-based model to predict cross-sectional variation in stock returns. The model implies mean reversion in stock prices if there is mean reversion in latent demand. Under the assumption that latent demand reverts to its unconditional expectation in the long run, we estimate long-run expected return for each stock. To test the ability of our variable to predict the cross section of stock returns, we run a Fama-MacBeth (1973) regression of monthly excess returns onto lagged characteristics, controlling for all characteristics in the Fama-French (2015) five-factor model as well as momentum. We find that our measure of long-run expected return uncovers a new source of predictability from mean reversion in latent demand. Expected monthly returns increase by 0.24 percent per one standard deviation in long-run expected return with a highly significant $t$-statistic above six.

The remainder of the paper is organized as follows. Section II derives the characteristics-based model from optimal portfolio choice. Section III describes the stock market and

---

institutional holdings data. Section IV explains our identifying assumptions and presents estimates of the asset demand system. Section V presents the empirical findings on the role of institutions in stock market movements, volatility, and predictability. Section VI discusses several extensions and open issues for future research. Section VII concludes. Appendix A contains proofs of all results in the main text.

II. Asset Pricing Model

We develop an asset pricing model from the optimal portfolio choice of investors that have heterogeneous beliefs and face short-sale constraints. We first review the derivation of the mean-variance portfolio, where the optimal portfolio varies across investors because of heterogeneous beliefs. We then show that the mean-variance portfolio simplifies to the characteristics-based model under a common assumption in empirical asset pricing, which is that returns have a factor structure and that expected returns and factor loadings depend only on the assets’ own characteristics. Finally, we estimate the mean-variance portfolio on stock market data to show the empirical relevance of the assumptions under which the mean-variance portfolio simplifies to the characteristics-based model.

A. Financial Assets

There are $N$ financial assets indexed by $n = 1, \ldots, N$. Let $S_t(n)$ be the number of shares outstanding of asset $n$ at date $t$. Let $P_t(n)$ and $D_t(n)$ be the price and dividend per share for asset $n$ at date $t$. Then $\text{ME}_t(n) = P_t(n)S_t(n)$ is market equity at date $t$, and $R_t(n) = (P_t(n) + D_t(n))/P_{t-1}(n)$ is the gross return from date $t-1$ to $t$. Let lowercase letters denote the logarithm of the corresponding uppercase variables. That is, $s_t(n) = \log(S_t(n))$, $p_t(n) = \log(P_t(n))$, $\text{me}_t(n) = \log(\text{ME}_t(n))$, and $r_t(n) = \log(R_t(n))$. We denote the $N$-dimensional vectors corresponding to these variables in bold as $s_t = \log(S_t)$, $p_t = \log(P_t)$, and $r_t = \log(R_t)$. We denote a vector of ones as $\mathbf{1}$, a vector of zeros as $\mathbf{0}$, an identity matrix as $\mathbf{I}$, and a diagonal matrix as $\text{diag}(\cdot)$ (e.g., $\text{diag}(\mathbf{1}) = \mathbf{I}$).

In addition to price and shares outstanding, the assets are differentiated along $K$ characteristics. In the case of stocks, for example, these characteristics could include various measures of fundamentals such as dividends, book equity, profitability, and investment. We denote characteristic $k$ of asset $n$ at date $t$ as $x_{k,t}(n)$. We stack these characteristics in an $N \times K$ matrix as $\mathbf{x}_t$, whose $n$th row is $\mathbf{x}_t(n)'$ and $(n, k)$th element is $x_{k,t}(n)$. To simplify notation, we follow the convention that the $K$th characteristic is a constant (i.e., $x_{K,t}(n) = 1$). Following the literature on asset pricing in endowment economies (Lucas 1978), we assume that shares outstanding, dividends, and other characteristics are exogenous. That is, only as-
set prices are endogenously determined in the model. Shares outstanding and characteristics could be endogenized in a production economy, as we discuss in Section VI.

B. Optimal Portfolio Choice

The financial assets are held by $I$ investors, indexed by $i = 1, \ldots, I$. Each investor allocates wealth $A_{i,t}$ at date $t$ across assets in its investment universe $\mathcal{N}_{i,t} \subseteq \{1, \ldots, N\}$ and an outside asset. The investment universe is a subset of assets that the investor is allowed to hold, which in practice is determined by an investment mandate. For example, the investment universe of an index fund is the set of assets that compose the index. We denote the number of assets in the investment universe as $|\mathcal{N}_{i,t}|$. The outside asset represents all wealth outside the $N$ assets that are the subject of our study. In an ideal data set, the outside asset would be comprehensive and include cash and bond positions if the subject of study is stocks. However, such data are not yet publicly available in the United States, as we discuss in Section III.

Let $w_{i,t}$ be an $|\mathcal{N}_{i,t}|$-dimensional vector of portfolio weights that investor $i$ chooses at date $t$.\footnote{Our notation presupposes that positions in redundant assets (with collinear payoffs) have been eliminated through aggregation so that the covariance matrix of log excess returns is invertible.} The investor chooses the portfolio weights at each date to maximize expected log utility over terminal wealth at date $T$:

$$\max_{w_{i,t}} \mathbb{E}_{i,t}[\log(A_{i,T})],$$

where $\mathbb{E}_{i,t}$ denotes investor $i$’s expectation at date $t$.\footnote{We assume log utility for expositional purposes because the multi-period portfolio-choice problem reduces to a one-period problem in which hedging demand is absent (Samuelson 1969).} Heterogeneous beliefs imply heterogeneous portfolios across investors in equilibrium. The law of motion for the investor’s wealth is

$$A_{i,t+1} = A_{i,t}(R_{t+1}(0) + w_{i,t}'(R_{t+1} - R_{t+1}(0)1)),\n$$

where $R_{t+1}(0)$ is the gross return on the outside asset. The investor also faces short-sale constraints:

$$w_{i,t} \geq 0,$$  \hspace{1cm} (1)

$$1'w_{i,t} < 1.$$  \hspace{1cm} (2)

Since the portfolio weight on the outside asset is $w_{i,t}(0) = 1 - 1'w_{i,t}$, constraint (2) rules out
leverage through the outside asset.

Let \( \Lambda_{i,t} \geq 0 \) and \( \lambda_{i,t} \geq 0 \) be the Lagrange multipliers on the short-sale constraints (1) and (2) at date \( t \). The Lagrangian for the portfolio-choice problem is

\[
L_{i,t} = \mathbb{E}_{i,t} \left[ \log(A_{i,T}) + \sum_{s=t}^{T-1} (\Lambda_{i,s} w_{i,s} + \lambda_{i,s}(1 - 1'w_{i,s})) \right].
\]  

We denote the conditional mean and covariance of log excess returns, relative to the outside asset, as

\[
\mu_{i,t} = \mathbb{E}_{i,t}[r_{t+1} - r_{t+1}(0) 1] + \frac{\sigma_{i,t}^2}{2},
\]

\[
\Sigma_{i,t} = \mathbb{E}_{i,t}[(r_{t+1} - r_{t+1}(0) 1 - \mathbb{E}_{i,t}[r_{t+1} - r_{t+1}(0) 1])(r_{t+1} - r_{t+1}(0) 1)'],
\]

where \( \sigma_{i,t}^2 \) is a vector of the diagonal elements of \( \Sigma_{i,t} \). Without loss of generality, we order and group the assets into those for which the short-sale constraint is not binding versus binding as

\[
w_{i,t} = \begin{bmatrix} w_{i,t}^{(1)} \\ 0 \end{bmatrix}, \quad \mu_{i,t} = \begin{bmatrix} \mu_{i,t}^{(1)} \\ \mu_{i,t}^{(2)} \end{bmatrix}, \quad \Sigma_{i,t} = \begin{bmatrix} \Sigma_{i,t}^{(1,1)} & \Sigma_{i,t}^{(1,2)} \\ \Sigma_{i,t}^{(2,1)} & \Sigma_{i,t}^{(2,2)} \end{bmatrix}.
\]  

The following lemma, proved in Appendix A, describes the solution to the portfolio-choice problem.

**Lemma 1.** The first-order condition for the portfolio-choice problem is the constrained Euler equation:

\[
\mathbb{E}_{i,t} \left[ \left( \frac{A_{i,t+1}}{A_{i,t}} \right)^{-1} R_{t+1} \right] = 1 - (I - 1'w_{i,t}'(\Lambda_{i,t} - \lambda_{i,t} 1)).
\]  

An approximate solution to the portfolio-choice problem is

\[
w_{i,t}^{(1)} \approx \Sigma_{i,t}^{(1,1)-1} (\mu_{i,t}^{(1)} - \lambda_{i,t} 1),
\]

where \( \lambda_{i,t} \) is given by equation (A6) in Appendix A.

Lemma 1 summarizes the known relation between Euler equations in asset pricing (5) and optimal portfolio choice (6). The right side of equation (5) simplifies to 1 when the investor is unconstrained (i.e., \( \Lambda_{i,t} = 0 \) and \( \lambda_{i,t} = 0 \)). Under this frictionless benchmark, we
impose rational expectations to obtain

\[ \mathbb{E}_t \left[ \left( \frac{A_{i,t+1}}{A_{i,t}} \right)^{-1} R_{t+1} \right] = 1. \]  

(7)

The literature on consumption-based asset pricing tests this moment condition on both aggregate and household consumption data. An important insight is that a test of equation (7) does not require household holdings data under the maintained null that investors are unconstrained and have rational expectations (Mankiw and Zeldes 1991; Brav, Constantinides, and Geczy 2002; Vissing-Jørgensen 2002).

As we show in Appendix A, equation (6) is based on an approximation of expected log utility around mean-variance utility. Therefore, we could justify equation (6) as an exact solution if we started with mean-variance utility, following a long tradition in portfolio choice (Markowitz 1952). Another common justification is that equation (6) is an exact solution in the continuous-time limit (Campbell and Viceira 2002, pp. 28–29).

C. Implementation of the Mean-Variance Portfolio

A benchmark implementation of the mean-variance portfolio would simply use the usual statistical formulas for sample mean and covariance. However, this approach leads to notoriously poor estimates of the mean-variance portfolio because of sampling error over many parameters (i.e., \( N \) parameters for the mean and \( N(N + 1)/2 \) parameters for the covariance matrix). A more robust approach to estimating the mean-variance portfolio exploits the factor structure in returns (MacKinlay and Pástor 2000) and the fact that expected returns and factor loadings are well captured by a few characteristics (Brandt, Santa-Clara, and Valkanov 2009).

Motivated by the intertemporal capital asset pricing model (Merton 1973) and arbitrage pricing theory (Ross 1976), a large literature has searched for a low-dimensional factor structure in returns. A notable contribution to this literature is the three-factor model of Fama and French (1993), in which the factors are the excess market returns, small minus big (SMB) portfolio returns, and high minus low (HML) book-to-market portfolio returns. The three-factor model suggests that expected returns and factor loadings are well captured by three characteristics: market beta, market equity (i.e., a measure of size), and book-to-market equity (i.e., a measure of value). A more recent five-factor model of Fama and French (2015) augments the three-factor model with two additional factors, which are robust minus weak (RMW) profitability portfolio returns and conservative minus aggressive (CMA) investment portfolio returns. The five-factor model implies that profitability and investment are two
additional characteristics that are relevant for expected returns and factor loadings.

We design an exercise that illustrates the empirical relevance of this literature for the
estimation of the mean-variance portfolio (6). In each month from December 1979 to November
2014, we estimate the mean-variance portfolio on the universe of S&P 500 stocks and
the 1-month T-bill as the outside asset, subject to short-sale constraints. In the benchmark
implementation, we estimate the sample mean and covariance of stock returns using a
60-month moving window. The first column of Table 1 reports that the benchmark imple-
mentation achieves monthly returns with a mean of 1.1 percent and a standard deviation of
4.5 percent. The certainty equivalent return under log utility (i.e., \(\exp\{\mathbb{E}[\log(A_{t+1}/A_t)]\} - 1\))
is 1.0 percent per month.

Following our discussion above of the empirical asset pricing literature, we can better
estimate the mean-variance portfolio (i.e., achieve a higher certainty equivalent return) by
exploiting the factor structure in returns and the fact that expected returns and factor
loadings are well captured by a few characteristics. In an alternative implementation, we
first estimate expected returns and factor loadings through a pooled ordinary least squares
regression of monthly excess returns, over the 1-month T-bill rate, onto excess market returns
using a 60-month moving window. The regression equation is

\[
 r_{t+1}(n) - r_{t+1}(0) = x_t(n)'\Phi + x_t(n)'\Psi f_{t+1} + \nu_{t+1}(n),
\]

where \(f_{t+1}\) is the market factor that is standardized over the 60-month moving window. The
\(K\)-dimensional vector \(\Phi\) determines the relation between expected returns and characteris-
tics, and the \(K\)-dimensional vector \(\Psi\) determines the relation between factor loadings and
characteristics. We standardize the characteristics in the cross section of stocks at each date
to address potential non-stationarity. The vector of expected returns and the covariance
matrix are

\[
\mathbb{E}_t[r_{t+1} - r_{t+1}(0)1] = x_t\Phi, \\
\Sigma_t = x_t\Psi'x_t' + \text{diag}(\text{Var}(\nu_{t+1})).
\]

Thus, the dimensionality of the mean-variance portfolio is reduced to only \(K\) parameters for
expected returns and \(K + N\) parameters for the covariance matrix.

Motivated by the Fama-French five-factor model, the characteristics that we use in the
alternative implementation are log market equity, log book equity, profitability, investment,
dividends to book equity, and market beta. We refer to Section III for a detailed description
of these variables. The second column of Table 1 reports that the alternative implementation
achieves monthly returns with a mean of 1.6 percent and a standard deviation of 6.3 percent.
The certainty equivalent return under log utility is 1.4 percent per month, which is higher than the 1.0 percent for the benchmark implementation. Our exercise essentially replicates the known result that exploiting the empirical relation between expected returns, factor loadings, and characteristics leads to better estimates of the mean-variance portfolio (Brandt, Santa-Clara, and Valkanov 2009; DeMiguel, Garlappi, and Uppal 2009).

D. Characteristics-Based Model

Under heterogeneous beliefs, different investors could form different expectations about returns based on the same observed characteristics. Furthermore, investor $i$ could form expectations about returns based on characteristics of asset $n$ at date $t$ that are unobserved to the econometrician, which we denote as $\log(\epsilon_{i,t}(n))$. We stack the relevant information set of investor $i$ for asset $n$ at date $t$ as

$$\hat{x}_{i,t}(n) = \begin{bmatrix} \text{me}_t(n) \\ x_t(n) \\ \log(\epsilon_{i,t}(n)) \end{bmatrix},$$

which consists of log market equity, other observed characteristics, and unobserved characteristics. We then form an $M$th-order polynomial of these characteristics through a $\sum_{m=1}^{M}(K+2)^m$-dimensional vector:

$$y_{i,t}(n) = \begin{bmatrix} \hat{x}_{i,t}(n) \\ \text{vec}(\hat{x}_{i,t}(n)\hat{x}_{i,t}(n)) \\ \vdots \end{bmatrix}.$$  

Following our discussion above of the empirical asset pricing literature, we assume that returns have a one-factor structure and that expected returns and factor loadings depend only on the assets' own characteristics.

**Assumption 1.** The covariance matrix of log excess returns is $\Sigma_{i,t} = \Gamma_{i,t} \Gamma_{i,t}' + \gamma_{i,t} I$, where $\Gamma_{i,t}$ is a vector of factor loadings and $\gamma_{i,t} > 0$ is idiosyncratic variance. Expected excess returns and factor loadings are polynomial functions of characteristics:

$$\mu_{i,t}(n) = y_{i,t}(n)' \Phi_{i,t} + \phi_{i,t},$$

$$\Gamma_{i,t}(n) = y_{i,t}(n)' \Psi_{i,t} + \psi_{i,t},$$

where $\Phi_{i,t}$ and $\Psi_{i,t}$ are vectors and $\phi_{i,t}$ and $\psi_{i,t}$ are scalars that are constant across assets.
The key content of Assumption 1 is that an asset’s characteristics are sufficient for its factor loadings, which also implies that they are sufficient for the variance of the optimal portfolio. We could relax the one-factor assumption and generalize to a multi-factor case, but the resulting expressions are less intuitive and less preferable for expositional purposes. The following proposition, proved in Appendix A, shows that the mean-variance portfolio simplifies to a polynomial function of characteristics under Assumption 1.

**Proposition 1.** Under Assumption 1, the optimal portfolio weight (6) on each asset \( n \) for which the short-sale constraint is not binding is

\[
\frac{w_{i,t}(n)}{w_{i,t}(0)} = y_{i,t}(n)\Pi_{i,t} + \pi_{i,t},
\]

(8)

where

\[
\Pi_{i,t} = \frac{1}{\gamma_{i,t}w_{i,t}(0)} \left( \Phi_{i,t} - \Psi_{i,t} \frac{\Gamma^{(1)}_{i,t}(\mu^{(1)}_{i,t} - \lambda_{i,t}1)}{\Gamma^{(1)}_{i,t}\Gamma^{(1)}_{i,t} + \gamma_{i,t}} \right),
\]

(9)

\[
\pi_{i,t} = \frac{1}{\gamma_{i,t}w_{i,t}(0)} \left( \phi_{i,t} - \lambda_{i,t} - \psi_{i,t} \frac{\Gamma^{(1)}_{i,t}(\mu^{(1)}_{i,t} - \lambda_{i,t}1)}{\Gamma^{(1)}_{i,t}\Gamma^{(1)}_{i,t} + \gamma_{i,t}} \right),
\]

and \( w_{i,t}(0) \) and \( \lambda_{i,t} \) are given by equations (A5) and (A6) in Appendix A.

In a portfolio-choice model, the investor ultimately cares about the tradeoff between risk (i.e., the covariance matrix) and expected return. Under Assumption 1, however, the investor indirectly cares about characteristics because they are sufficient for the covariance matrix and expected returns. The vector \( \Pi_{i,t} \) and scalar \( \pi_{i,t} \) are functions of characteristics through three scalars (i.e., \( w_{i,t}(0) \), \( \lambda_{i,t} \), and the term after \( \Psi_{i,t} \)). However, the key content of equation (8) is that \( \Pi_{i,t} \) and \( \pi_{i,t} \) are constant across assets. Therefore, the only reason that the portfolio weights vary across assets in equation (8) is that the vector of characteristics \( y_{i,t}(n) \) varies across assets.

Equation (9) for the coefficients on characteristics has an intuitive interpretation. Because the term after \( \Psi_{i,t} \) is a scalar, the investor’s demand for characteristics is simply a linear combination of the vectors on expected returns \( \Phi_{i,t} \) and factor loadings \( \Psi_{i,t} \). That is, the investor prefers assets with characteristics that are associated with higher expected returns or smaller factor loadings (i.e., less risk).

Equation (8) is an \( M \)th-order polynomial of characteristics. If we were to view it as an estimation equation, we would need to impose some coefficient restrictions on \( \Pi_{i,t} \) to reduce the dimensionality of the estimation problem. In Appendix A, we show that a particular
coefficient restriction implies that equation (8) is an $M$th-order polynomial expansion of the exponential function. As a matter of specification, a model of portfolio weights that is exponential-linear in characteristics is parsimonious and pairs nicely with the fact that portfolio weights appear log-normal in the 13F data. Thus, we have the following corollary to Proposition 1.

**COROLLARY 1.** A restricted version of the mean-variance portfolio (8) under Assumption 1 is the characteristics-based model:

$$
\frac{w_{i,t}(n)}{w_{i,t}(0)} = \delta_{i,t}(n) = \exp\left\{\beta_{0,i,t} \text{me}_t(n) + \sum_{k=1}^{K-1} \beta_{k,i,t} x_{k,t}(n) + \beta_{K,i,t} \right\} \epsilon_{i,t}(n).
$$

Equation (10) and the budget constraint imply that investor $i$’s portfolio weight on asset $n \in \mathcal{N}_{i,t}$ at date $t$ is

$$
w_{i,t}(n) = \frac{\delta_{i,t}(n)}{1 + \sum_{m \in \mathcal{N}_{i,t}} \delta_{i,t}(m)}. \tag{11}
$$

The portfolio weight on the outside asset is

$$
w_{i,t}(0) = \frac{1}{1 + \sum_{m \in \mathcal{N}_{i,t}} \delta_{i,t}(m)}. \tag{12}
$$

Although there are $|\mathcal{N}_{i,t}| + 1$ assets including the outside asset, there are only $|\mathcal{N}_{i,t}|$ degrees of freedom because of the budget constraint.

We refer to equation (10) as the characteristics-based model because the portfolio weights depend on log market equity, other observed characteristics, and unobserved characteristics. Price per share enters demand only through market equity because the number of shares outstanding is not economically meaningful. We follow the notational convention that the $K$th characteristic is a constant (i.e., $x_{K,t}(n) = 1$) so that $\beta_{K,i,t}$ is the intercept. We refer to $\epsilon_{i,t}(n)$ as *latent demand*, which captures investor $i$’s demand for unobserved (to the econometrician) characteristics of asset $n$. As we discuss in Section III, we do not observe short positions in our empirical application. Therefore, we restrict $\epsilon_{i,t}(n) \geq 0$ so that the portfolio weights are positive.

We normalize the mean of latent demand $\epsilon_{i,t}(n)$ to one so that the intercept $\beta_{K,i,t}$ in equation (10) is identified. Then the intercept $\beta_{K,i,t}$ and latent demand $\epsilon_{i,t}(n)$ play different roles in equation (10). On the one hand, $\beta_{K,i,t}$ determines demand for all assets in the investment universe relative to the outside asset. In equation (12), the portfolio weight on the outside asset is decreasing in $\beta_{K,i,t}$. On the other hand, cross-sectional variation in $\epsilon_{i,t}(n)$
captures relative demand across assets in the investment universe.

The characteristics-based model can easily capture an index fund. Suppose that $\beta_{0,i,t} = 1$, $\beta_{k,i,t} = 0$ for $k = 1, \ldots, K - 1$, and $\epsilon_{i,t}(n) = 1$ for all assets $n \in \mathcal{N}_{i,t}$. Then equations (11) and (12) simplify to

$$
\begin{align*}
\quad w_{i,t}(n) &= \frac{\text{ME}_t(n)}{\exp\{-\beta_{K,i,t}\} + \sum_{m \in \mathcal{N}_{i,t}} \text{ME}_t(m)}, \\
\quad w_{i,t}(0) &= \frac{\exp\{-\beta_{K,i,t}\}}{\exp\{-\beta_{K,i,t}\} + \sum_{m \in \mathcal{N}_{i,t}} \text{ME}_t(m)}.
\end{align*}
$$

In this special case, the investor is an index fund whose portfolio weights are proportional to market equity, and the intercept $\beta_{K,i,t}$ determines the portfolio weight on the outside asset.

Because the characteristics-based model is derived from the mean-variance portfolio, the substitution effects implied by the model are consistent with optimal portfolio choice. To illustrate this empirically, we return to the exercise in Table 1. We consider a special case of equation (10) without latent demand by setting $\epsilon_{i,t}(n) = 1$ for all assets $n \in \mathcal{N}_{i,t}$. We then estimate the coefficients on characteristics by ordinary least squares to best match the portfolio weights under the factor-structure approach in the second column. Again, the characteristics that we use are log market equity, log book equity, profitability, investment, dividends to book equity, and market beta. The third column of Table 1 reports that the characteristics-based model achieves the same mean, standard deviation, and certainty equivalent return (up to rounding at 0.1 percent) as the factor-structure approach. The correlation in monthly returns between the factor-structure approach and the characteristics-based model is 0.95.

In summary, Table 1 teaches us two lessons about implementing the mean-variance portfolio. First, the improvement in certainty equivalent return from the first to the second column teaches us the importance of exploiting the factor structure in returns and the fact that expected returns and factor loadings are well captured by a few characteristics. Second, the negligible difference in certainty equivalent return between the second and third columns teaches us that an exponential-linear function of characteristics closely captures the mean-variance portfolio. These results together show that the characteristics-based model is an implementation of the mean-variance portfolio with good empirical performance.

E. Demand Elasticities

In equation (10), the coefficients on characteristics are indexed by $i$ and, therefore, vary across investors. In particular, investors have heterogeneous demand elasticities. Let $q_{i,t} = \log(\mathbf{A}_{i,t} \mathbf{w}_{i,t}) - \mathbf{p}_t$ be the vector of log shares held by investor $i$, defined only over the subvector
of strictly positive portfolio weights. The elasticity of individual demand is

$$- \frac{\partial q_{i,t}}{\partial p_i'} = I - \beta_{0,i,t} \text{diag}(w_{i,t})^{-1} G_{i,t},$$

(14)

where $G_{i,t} = \text{diag}(w_{i,t}) - w_{i,t} w_{i,t}'$. Demand elasticity is decreasing in $\beta_{0,i,t}$. Returning to our example in equation (13), an index fund with $\beta_{0,i,t} = 1$ has inelastic demand.

Let $q_t = \log(\sum_{i=1}^{I} A_{i,t} w_{i,t}) - p_t$ be the vector of log shares held across all investors, summed only over the subvectors of strictly positive portfolio weights. The elasticity of aggregate demand is

$$- \frac{\partial q_t}{\partial p_i'} = I - \sum_{i=1}^{I} A_{i,t} \beta_{0,i,t} H_t^{-1} G_{i,t},$$

(15)

where $H_t = \sum_{i=1}^{I} A_{i,t} \text{diag}(w_{i,t})$. The diagonal elements of matrices (14) and (15) are strictly positive when $\beta_{0,i,t} < 1$ for all investors. Thus, the following assumption is sufficient for both individual and aggregate demand to be downward sloping.

**Assumption 2.** The coefficient on log market equity satisfies $\beta_{0,i,t} < 1$ for all investors.

In most asset pricing models, demand is downward sloping for various reasons including risk aversion, hedging motives (Merton 1973), and price impact (Wilson 1979; Kyle 1989). As we show next, Assumption 2 is also sufficient for the existence and uniqueness of equilibrium. Therefore, we maintain Assumption 2 for convenience in our implementation of the characteristics-based model.

**F. Market Clearing**

We complete the asset pricing model with market clearing for each asset $n$:

$$\text{ME}_t(n) = \sum_{i=1}^{I} A_{i,t} w_{i,t}(n).$$

(16)

That is, the market value of shares outstanding must equal the wealth-weighted sum of portfolio weights across all investors. In equation (16) and throughout the paper, we follow the notational convention that $w_{i,t}(n) = 0$ for any asset that is not in investor $i$’s investment universe (i.e., $n \notin N_{i,t}$). If asset demand were homogeneous, market clearing (16) implies that all investors hold the market portfolio in equilibrium, just as in the capital asset pricing model (CAPM) (Sharpe 1964; Lintner 1965). In contrast, the characteristics-based model
accommodates rich heterogeneity in asset demand across investors and matches institutional holdings.

We rewrite market clearing (16) in logarithms and vector notation as

$$\mathbf{p} = f(\mathbf{p}) = \log \left( \sum_{i=1}^{I} A_i \mathbf{w}_i(\mathbf{p}) \right) - \mathbf{s}. \quad (17)$$

In this equation and the remainder of this section, we drop time subscripts to simplify notation. Assumption 2 is sufficient for the existence and uniqueness of equilibrium. That is, the equilibrium price vector is well defined, regardless of the distribution of parameters and characteristics.

**Proposition 2.** Under Assumption 2, $f(\mathbf{p})$ has a unique fixed point in $\mathbb{R}^N$.

The proof of Proposition 2 in Appendix A proceeds by showing that the function $\mathbf{p} - f(\mathbf{p})$ is globally invertible under Assumption 2. We emphasize that Assumption 2 is a sufficient condition and that a unique equilibrium could exist even when $\beta_{0,i} \geq 1$ for some investors. Although Proposition 2 guarantees a unique equilibrium, we still need an algorithm for computing the equilibrium price vector in applications. Appendix B describes an efficient algorithm for computing the equilibrium in any counterfactual experiment, which we have developed for the empirical applications in Section V.

Of course, the use of the characteristics-based model for policy experiments is valid only under the null that it is a structural model that is policy invariant. The Lucas (1976) critique applies under the alternative that the coefficients on characteristics ultimately capture beliefs or constraints that change with policy. Furthermore, we cannot answer welfare questions without taking an explicit stance on preferences, beliefs, and constraints. However, this may not matter for most asset pricing applications in which price (rather than welfare) is the primary object of interest. The remainder of the paper proceeds under the assumption that the characteristics-based model is a structural model of asset demand, which is motivated by Corollary 1.

### III. Stock Market and Institutional Holdings Data

#### A. Stock Characteristics

The data on stock prices, dividends, returns, and shares outstanding are from the Center for Research in Security Prices (CRSP) Monthly Stock Database. We restrict our sample to ordinary common shares (i.e., share codes 10, 11, 12, and 18) that trade on NYSE, AMEX, and Nasdaq (i.e., exchange codes 1, 2, and 3). We further restrict our sample to stocks with
non-missing price and shares outstanding. Accounting data are from the Compustat North America Fundamentals Annual Database. We merge the CRSP data with the most recent Compustat data as of at least 6 months and no more than 24 months prior to the trading date. The lag of at least 6 months ensures that the accounting data were public on the trading date.

In addition to log market equity, the characteristics in our specification include log book equity, profitability, investment, dividends to book equity, and market beta. Our choice of book equity, profitability, and investment is motivated by the Fama-French five-factor model that is known to describe the cross section of stock returns. Dividends and market beta have a long tradition in empirical asset pricing as measures of fundamentals and systematic risk, respectively. Our specification is based on a parsimonious and relevant set of characteristics for explaining expected returns and factor loadings, motivated by Assumption 1. We are concerned about collinearity between characteristics and overfitting if we consider a larger model with more characteristics. We stay away from return variables because they could violate our identifying assumption that characteristics other than price are exogenous to latent demand, as we discuss in Section IV. In addition, Hou, Xue, and Zhang (2015) find that characteristics that are already in our specification absorb the explanatory power of some return variables (e.g., profitability absorbs momentum and book-to-market equity absorbs long-term reversal).

Our construction of these characteristics follows Fama and French (2015), which we briefly summarize here. Profitability is the ratio of operating profits to book equity. Investment is the annual log growth rate of assets. Dividends to book equity is the ratio of annual dividends per split-adjusted share times shares outstanding to book equity. We estimate market beta from a regression of monthly excess returns, over the 1-month T-bill rate, onto excess market returns using a 60-month moving window (with at least 24 months of non-missing returns). At each date, we winsorize profitability, investment, and market beta at the 2.5th and 97.5th percentiles to reduce the impact of large outliers. Since dividends are positive, we winsorize dividends to book equity at the 97.5th percentile.

Following Fama and French (1992), our analysis focuses on ordinary common shares that are not foreign or a real estate investment trust (i.e., share code 10 or 11) and have non-missing characteristics and returns. In our terminology, these are the stocks that make up the investment universe. The outside asset includes the complement set of stocks, which are either foreign (i.e., share code 12), real estate investment trusts (i.e., share code 18), or have missing characteristics or returns.

---

4Operating profits are annual revenues minus the sum of cost of goods sold; selling, general, and administrative expenses; and interest and related expenses.
B. Institutional Stock Holdings

The data on institutional common stock holdings are from the Thomson Reuters Institutional Holdings Database (s34 file), which are compiled from the quarterly filings of Securities and Exchange Commission Form 13F. All institutional investment managers that exercise investment discretion on accounts holding Section 13(f) securities, exceeding $100 million in total market value, must file the form. Form 13F reports only long positions and not short positions. We also do not know the cash and bond positions of institutions because these assets are not 13(f) securities.

We group institutions into six types: banks, insurance companies, investment advisors, mutual funds, pension funds, and other 13F institutions. An investment advisor is a registered company under Securities and Exchange Commission Form ADV. Investment advisors include many hedge funds, and we separate investment advisors that are mutual funds into a different group. The group of other 13F institutions includes endowments, foundations, and nonfinancial corporations. Appendix C contains details of how we construct the institution type.

We merge the institutional holdings data with the CRSP-Compustat data by CUSIP number and drop any holdings that do not match (i.e., 13(f) securities whose share codes are not 10, 11, 12, or 18). We compute the dollar holding for each stock that an institution holds as price times shares held. Assets under management is the sum of dollar holdings for each institution. We compute the portfolio weights as the ratio of dollar holdings to assets under management.

We define the investment universe for each institution at each date as stocks that are currently held or ever held in the previous seven quarters. Thus, the investment universe includes a zero holding whenever a stock that was held in the previous seven quarters is no longer in the portfolio. To motivate our choice of seven quarters, Table 2 reports the percentage of stocks held in the current quarter that were ever held in the previous one to seven quarters. For the median institution in assets under management, 96 percent of stocks that are currently held were held in the previous quarter. This percentage increases to 97 percent at four quarters and remains stable at longer horizons, so that going beyond four quarters does not substantively change our measure of the investment universe.

Market clearing (16) requires that shares outstanding equal the sum of shares held across all investors. For each stock, we define the shares held by the household sector as the difference between shares outstanding and the sum of shares held by 13F institutions.\footnote{In a small number of cases, the sum of shares reported by 13F institutions exceeds shares outstanding, which may be due to shorting or reporting errors (Lewellen 2011). In these cases, we scale down the reported holdings of all 13F institutions to ensure that the sum equals shares outstanding.}

\[ \text{Market clearing} \]

\[ \text{shares outstanding} = \text{sum of shares held across all investors} \]

\[ \text{shares held by household sector} = \text{shares outstanding} - \text{sum of shares held by 13F institutions} \]

The
household sector represents direct household holdings and smaller institutions that are not
required to file Form 13F. We also include as part of the household sector any institution
with less than $10 million in assets under management, no stocks in the investment universe,
or no outside assets.

Table 3 summarizes the 13F institutions in our sample from 1980 to 2014. In the be-
inning of the sample, there were 544 institutions that managed 35 percent of the stock
market. This number grows steadily to 2,832 institutions that managed 63 percent of the
stock market by the end of the sample. From 2010 to 2014, the median institution man-
aged $325 million, while larger institutions at the 90th percentile managed $5,483 million.
Most institutions hold concentrated portfolios. From 2010 to 2014, the median institution
held 67 stocks, while the more diversified institutions at the 90th percentile held 444 stocks.
Table C1 in Appendix C contains a more detailed breakdown of Table 3 by institution type.

IV. Estimating the Asset Demand System

Equation (10) can be interpreted as a nonlinear regression model that relates the cross section
of portfolio weights to characteristics. A lower coefficient on log market equity means that
demand is more elastic. For example, an investor that tilts its portfolio toward value stocks
would have a low coefficient on log market equity and a high coefficient on log book equity.
The goal of this section is to identify the coefficients on characteristics in equation (10) for
each investor at each date. We drop time subscripts throughout this section to simplify
notation and to emphasize that estimation is on the cross section of assets. We impose
the coefficient restriction $\beta_{0,i} < 1$ to ensure that demand is downward sloping and that
equilibrium is unique (see Proposition 2).

A. Identifying Assumptions

1. Exogenous Characteristics

Our starting point is the identifying assumption that is implied by the literature on asset
pricing in endowment economies (Lucas 1978):

$$\mathbb{E}[\epsilon_i(n)|\text{me}(n), \text{x}(n)] = 1.$$  (18)

Equation (10) could be estimated by nonlinear least squares under this moment condition,
which describes most of the empirical literature on household portfolio choice and cross-
border capital flows in international finance. Following this literature, we retain the assump-
tion that shares outstanding and characteristics other than price are exogenous, determined
by an exogenous endowment process.

The usual justification for the exogeneity of prices (or market equity) in moment condition (18) is that the investor is atomistic so that demand shocks have negligible price impact. However, even if individual investors are atomistic, correlated demand shocks could have price impact in the aggregate, so moment condition (18) rules out any factor structure in latent demand. Because these assumptions are unlikely to hold for institutional investors or households, we develop an alternative identification strategy based on weaker assumptions.

2. Investment Mandates and the Wealth Distribution

Let $\mathbb{I}_i(n)$ be an indicator function that is equal to one if asset $n$ is in investor $i$’s investment universe (i.e., $n \in \mathcal{N}_i$). We can trivially rewrite equation (10) for any asset as

$$
\frac{w_i(n)}{w_i(0)} = \begin{cases} 
\mathbb{I}_i(n) \exp \left\{ \beta_{0,i} \text{me}(n) + \sum_{k=1}^{K-1} \beta_{k,i} x_k(n) + \beta_{K,i} \right\} \epsilon_i(n) & \text{if } n \in \mathcal{N}_i \\
\mathbb{I}_i(n) = 0 & \text{if } n \notin \mathcal{N}_i
\end{cases}
$$

This notation emphasizes that there are two possible reasons that an investor does not hold an asset. The first reason is that the investor is not allowed to hold the asset because it is not in its investment universe (i.e., $\mathbb{I}_i(n) = 0$). For example, an index fund cannot hold assets that are outside the index. The second reason is that the investor chooses not to hold an asset even though it could (i.e., $\epsilon_i(n) = 0$). For example, an index fund may choose not to hold an asset in the index that is perceived to be overvalued. Thus, $\mathbb{I}_i(n)$ is exogenous under the maintained assumption that the investment universe is exogenous, while $\epsilon_i(n)$ is endogenous through the portfolio-choice problem.

In practice, the investment universe is defined by an investment mandate, which is a predetermined rule on the set of investable assets. For example, the investment mandate of a technology fund limits the investment universe to technology stocks. The key economic property of an investment mandate is that it is a predetermined rule that is plausibly exogenous to current demand shocks. Appendix D contains some examples of mutual funds for which the prospectus clearly states the investment mandate. Other types of institutions such as insurance companies, pension funds, and hedge funds also use investment mandates even though they are usually not publicly disclosed (Sharpe 1981; Binsbergen, Brandt, and Koijen 2008; Blake et al. 2013).

In addition to the investment universe, we maintain the assumption that the wealth distribution across other investors is predetermined and exogenous to current demand shocks. While this assumption ultimately appeals to a static view of portfolio choice, it has some empirical content. Hortaçsu and Syverson (2004) find significant variation in assets under
management across similar mutual funds that remains unexplained by differences in fees (or expected returns).

3. Instrumental Variables

We describe how to construct a valid instrument for log market equity in an ideal scenario that the investment universe is perfectly measured. In the following section, we will come back to the issue of measuring the investment universe in practice.

In estimating investor $i$’s asset demand, the instrument for log market equity of asset $n$ is

$$
\hat{\mu}_i(n) = \log \left( \sum_{j \neq i} A_j \frac{\mathbb{1}_j(n)}{1 + \sum_{m=1}^{N} \mathbb{1}_j(m)} \right). \tag{19}
$$

This instrument depends only on the investment universe of other investors and the wealth distribution, which are exogenous under our identifying assumptions. The instrument can be interpreted as the counterfactual market equity, at the market clearing price, if other investors were to hold an equal-weighted portfolio within their investment universe. For example, technology funds hold an equal-weighted portfolio of technology stocks, health care funds hold an equal-weighted portfolio of health care stocks, and so on.

The instrument exploits the variation in the investment universe across investors and the size of potential investors across assets. An asset that is included in the investment universe of more investors, especially if those investors are large, has a larger exogenous component of demand. For example, a stock that is included in the S&P 500 index has a larger exogenous component of demand coming from S&P 500 index funds (Harris and Gurel 1986; Shleifer 1986). With downward-sloping demand, a larger exogenous component of demand generates higher prices that are unrelated to latent demand. Our identification comes from cross-sectional variation in the investment universe and not from time-series variation in assets moving in and out of the investment universe.

The instrument allows us to weaken moment condition (18) to

$$
\mathbb{E}[\epsilon_i(n)|\hat{\mu}_i(n), x(n)] = 1. \tag{20}
$$

This moment condition does not impose any assumptions on the correlation of latent demand across investors or over time. Given the presence of zero holdings in the data, latent demand has a positive mass at zero. However, a conditional mean of one in moment condition (20) is a normalization that is fully consistent with the presence of zero holdings.\(^6\)

\(^6\)In particular, the probability that latent demand is zero depends on characteristics, which is consistent
B. Implementation Issues

1. Measuring the Investment Universe

With the exception of some mutual funds for which the investment mandate is clearly stated (see Appendix D), most institutions do not publicly disclose investment mandates. We must therefore measure the investment universe based on observed holdings. As we described in Section III, we measure the investment universe as stocks that are currently held or ever held in the previous seven quarters.

The ideal scenario for arguing the exogeneity of the measured investment universe is if it did not change over time. A time-invariant investment universe lends credibility to our identifying assumption that it is predetermined and exogenous to current demand shocks. Table 2 shows that the investment universe is not that far from the ideal scenario, especially for larger institutions. For a larger institution at the 90th percentile in assets under management, 99 out of every 100 stocks that they currently hold were part of the investment universe in the previous quarter as well. Thus, the potential threat to identification is isolated to the one stock that newly entered the investment universe. The fact that the set of stocks held hardly changes over time is consistent with the presence of investment mandates.

We refine the instrument (19) to be more robust to the potential threat to identification. Insofar as the investment universe is mis-measured, it is likely to be so for groups of institutions that have common relative performance evaluation or capital regulation (in the case of banks and insurance companies). Therefore, we group institutions by type (i.e., banks, insurance companies, investment advisors, mutual funds, pension funds, and other 13F institutions) and quantiles of assets under management conditional on type. We then construct the instrument for investor \(i\) by aggregating only over investors that are outside investor \(i\)'s group.

Although we have tried to make the best case for identification, we want to summarize our remaining concerns with the hope that future research could make further progress. By definition, the investment universe is a broader set of stocks than those that are held in the recent past. Thus, we are concerned that our definition of the investment universe may miss some stocks that could be held but have not been held in the recent past. Any correlation between this mis-measurement and latent demand through correlated demand with the portfolio-choice model in Section II. To see this, we can rewrite moment condition (18) as

\[
E[\epsilon_i(n)|\hat{\mu}_c(n), x(n)] = Pr(\epsilon_i(n) = 0|\hat{\mu}_c(n), x(n)) \underbrace{E[\epsilon_i(n)|\hat{\mu}_c(n), x(n), \epsilon_i(n) = 0]}_{0} \\
+ Pr(\epsilon_i(n) > 0|\hat{\mu}_c(n), x(n))E[\epsilon_i(n)|\hat{\mu}_c(n), x(n), \epsilon_i(n) > 0] = 1.
\]
shocks across investors could threaten identification. Future research could improve upon our framework through new data or methodology that leads to better measurement of the investment universe.

2. Pooled Estimation

Table 3 shows that many institutions have concentrated portfolios, so the cross section of an institution’s holdings may not be large enough to accurately estimate the coefficients in equation (10). We estimate the coefficients by institution whenever there are more than 1,000 strictly positive holdings in the cross section. For institutions with fewer than 1,000 holdings, we pool them with similar institutions in order to estimate their coefficients. As we described above, we group institutions by type and quantiles of assets under management conditional on type. While the cutoff of 1,000 is arbitrary, a lower cutoff of 500 causes convergence problems for our estimator in some cases. We set the total number of groups at each date to target 2,000 strictly positive holdings on average per group.

3. Weak Instruments

Cross-sectional variation in the instrument (19) is primarily driven by variation in the investment universe across investors. Put differently, the instrument would have no variation if the investment universe were identical across investors. Fortunately, from an identification perspective, Table 3 shows that the investment universe is typically a small set of stocks. From 2010 to 2014, the median institution had only 105 stocks in the investment universe, and even institutions at the 90th percentile had only 683 stocks.

A way to quantify the strength of the instrument is through a first-stage regression of log market equity onto the instrument and other characteristics. We estimate the first-stage regression for each institution at each date. Figure 1 reports the minimum first-stage $t$-statistic across institutions at each date. That is, all institutions have a first-stage $t$-statistic that is above the lower bound in the figure. For all institutions throughout the sample period, the first-stage $t$-statistic is well above the critical value of 4.05 for rejecting the null of weak instruments (Stock and Yogo 2005, Table 5.2).

C. Estimation on a Hypothetical Index Fund

We test the validity of our estimator for the characteristics-based model (10) on a hypothetical index fund. We start with the portfolio weights of the Vanguard Group (manager number 90457), which has a fully diversified portfolio, and replace them with exact market weights. That is, we construct an index fund that is the same size and has the same
investment universe as the Vanguard Group, whose portfolio weights are given by

\[
\frac{w_i(n)}{w_i(0)} = \exp\{\text{me}(n) + \beta_{K,i}\}
\]

\[
= \exp\{\text{me}(n) - \text{be}(n) + \text{be}(n) + \beta_{K,i}\},
\]

where \(\text{be}(n)\) is log book equity. We then estimate the characteristics-based model (10) by generalized method of moments (GMM) under moment condition (20). If our estimator is valid, we should recover a coefficient of one on log market equity and zero on the other characteristics. Equivalently, we should recover a coefficient of one on both log market-to-book equity and log book equity based on the alternative normalization (21).

Figure 2 reports the estimated coefficients for the hypothetical index fund. As expected, we recover a coefficient of one on both log market-to-book equity and log book equity and zero on the other characteristics, except for small deviations due to estimation error.

D. Estimated Demand System

Figure 3 summarizes the coefficients for the characteristics-based model (10), estimated by GMM under moment condition (20). We report the cross-sectional mean of the estimated coefficients by institution type, weighted by assets under management. For ease of interpretation, Figure 3 is on the same scale as Figure 2 and reports the coefficients on log market-to-book equity \(\beta_{0,i}\) and log book equity \(\beta_{0,i} + \beta_{1,i}\) instead of \(\beta_{0,i}\) and \(\beta_{1,i}\).

A lower coefficient on log market-to-book equity implies a higher demand elasticity (14). Thus, Figure 3 shows that mutual funds have less elastic demand than other types of institutions or households for most of the sample period. Banks, insurance companies, and pension funds have become less elastic from 1980 to 2014, while investment advisors and households have become more elastic during the same period. In 2014, banks, insurance companies, mutual funds, and pension funds have less elastic demand than investment advisors and households. This finding is consistent with the view that large institutions cannot deviate too far from market weights because of benchmarking or price impact.

The coefficient on log book equity captures demand for size. Especially in the second half of the sample period, banks and insurance companies tilt their portfolio toward larger stocks than other types of institutions. In contrast, investment advisors tilt their portfolio toward smaller stocks. Table C1 of Appendix C shows that the largest investment advisors are an order of magnitude smaller than other types of large institutions. Therefore, our findings are consistent with the fact that the size of institutions is positively related to the average size of stocks in their portfolio (Blume and Keim 2012).
On average, institutions tilt their portfolio toward stocks with higher profitability, lower investment, and lower market beta than households. As we discussed in Section II, these characteristics enter the Fama-French five-factor model and are known to generate positive abnormal returns relative to the CAPM. Therefore, this finding is consistent with the view that some institutions are “smart money” investors. The coefficient on market beta for institutions tends to fall in recessions, which means that the demand for market risk is procyclical. For example, the coefficient on market beta for investment advisors is low in 1982:3, 2001:3, and 2009:1. Finally, households tilt their portfolio toward higher dividend stocks than institutions. Among institutions, banks tilt their portfolio toward higher dividend stocks than other types of institutions.

Given the estimated coefficients, we recover estimates of latent demand by equation (10). Figure 4 reports the cross-sectional standard deviation of log latent demand by institution type, weighted by assets under management. A higher standard deviation implies more extreme portfolio weights that are tilted away from observed characteristics. For most of the sample period, households have less variation in latent demand than institutions. The only exception is during the financial crisis, when the standard deviation of latent demand for households peaked in 2008:2.

In Appendix E, we show that our benchmark estimates differ from those estimated by alternative estimators. We show the importance of the instrument by considering a restricted least squares estimator that is biased if latent demand and asset prices are jointly endogenous. We also show the importance of estimating in levels with zero holdings by considering estimation of equation (10) in logarithms, which is less efficient and potentially biased.

V. Asset Pricing Applications

Let $A_t$ be an $I$-dimensional vector of investors’ wealth, whose $i$th element is $A_{i,t}$. Let $\beta_t$ be a $(K + 1) \times I$ matrix of coefficients on characteristics, whose $(k, i)$th element is $\beta_{k-1,i,t}$. Let $\epsilon_t$ be an $N \times I$ matrix of latent demand, whose $(n, i)$th element is $\epsilon_{i,t}(n)$. Market clearing (17) defines an implicit function for log price:

$$p_t = g(s_t, x_t, A_t, \beta_t, \epsilon_t).$$

That is, asset prices are fully determined by shares outstanding, characteristics, the wealth distribution, the coefficients on characteristics, and latent demand.

We use equation (22) in four asset pricing applications. First, we use the model to estimate the price impact of demand shocks for all institutions and stocks. Second, we use the model to decompose the cross-sectional variance of stock returns into supply- and
demand-side effects. Third, we use a similar variance decomposition to see whether larger institutions explain a disproportionate share of the stock market volatility in 2008. Finally, we use the model to predict cross-sectional variation in stock returns.

A. Price Impact of Demand Shocks

If the aggregate demand for stocks is downward sloping, demand shocks could have persistent effects on prices. For example, an empirical literature documents the price impact of demand shocks that arise from index additions and deletions (see Wurgler and Zhuravskaya 2002, for a review). The estimated demand system in Section IV allows us to estimate the price impact of demand shocks for all stocks, not just for those that are added or deleted from an index.

We define the coliquidity matrix for investor $i$ as

$$\frac{\partial p_t}{\partial \log(\epsilon_{i,t})}' = \left( I - \sum_{j=1}^{I} A_{j,t} H_{t}^{-1} \frac{\partial w_{j,t}}{\partial p_t}' \right)^{-1} A_{i,t} H_{t}^{-1} \frac{\partial w_{i,t}}{\partial \log(\epsilon_{i,t})}'$$

$$= \left( I - \sum_{j=1}^{I} A_{j,t} \beta_{0,j,t} H_{t}^{-1} G_{j,t} \right)^{-1} A_{i,t} H_{t}^{-1} G_{i,t}. \quad (23)$$

The $(n,m)$th element of this matrix is the elasticity of asset price $n$ with respect to investor $i$’s latent demand for asset $m$. The coliquidity matrix measures the price impact of idiosyncratic shocks to an investor’s latent demand. The matrix inside the inverse in equation (23) is the aggregate demand elasticity (15), which implies larger price impact for assets that are held by less elastic investors. The $n$th diagonal element of the matrix outside the inverse in equation (23) is $A_{i,t} w_{i,t}(n)(1 - w_{i,t}(n)) / (\sum_{j=1}^{I} A_{j,t} w_{j,t}(n))$. This expression implies larger price impact for investors whose holdings are large relative to other investors that hold the asset.

We estimate the price impact for each stock and institution through the diagonal elements of matrix (23) and then average by institution type. Figure 5 summarizes the cross-sectional distribution of price impact across stocks for the average bank, insurance company, investment advisor, mutual fund, and pension fund. Average price impact has decreased from 1980 to 2014, especially for the least liquid stocks at the 90th percentile of the distribution. This means that the cross-sectional distribution of price impact has significantly compressed

---

7Kondor and Vayanos (2014) propose a liquidity measure that is a monotonic transformation of our measure:

$$\left( \frac{\partial q_{i,t}(n)}{\partial \log(\epsilon_{i,t}(n))} \right)^{-1} \frac{\partial p_t(n)}{\partial \log(\epsilon_{i,t}(n))} = \left( 1 - w_{i,t}(n) \right) \left( \frac{\partial p_t(n)}{\partial \log(\epsilon_{i,t}(n))} \right)^{-1} - 1 \right)^{-1}.$$
over this period. For example, the price impact for the average investment advisor with a 10 percent demand shock on the least liquid stocks (at the 90th percentile) has decreased from 0.87 percent in 1980:2 to 0.25 percent in 2014:2.

Summing equation (23) across all investors, we define the aggregate coliquidity matrix as

$$\sum_{i=1}^{I} \frac{\partial p_t}{\partial \log(e_{i,t})}' = \left( I - \sum_{i=1}^{I} A_{i,t} \beta_{0,i,t} H_t^{-1} G_{i,t} \right)^{-1} \sum_{i=1}^{I} A_{i,t} H_t^{-1} G_{i,t}. \tag{24}$$

The aggregate coliquidity matrix measures the price impact of systematic shocks to latent demand across all investors. The $n$th diagonal element of the matrix outside the inverse in equation (24) is a holdings-weighted average of $1 - w_{i,t}(n)$ across investors. This implies larger price impact for assets that are smaller shares of investors’ wealth, which are effectively assets with lower market cap.

We estimate the aggregate price impact for each stock through the diagonal elements of matrix (24). Figure 6 summarizes the cross-sectional distribution of aggregate price impact across stocks and how that distribution has changed over time. Aggregate price impact has decreased from 1980 to 2014. For the median stock, the price impact of a 10 percent aggregate demand shock has decreased from 33 percent in 1980:2 to 26 percent in 2014:2. Aggregate price impact is strongly countercyclical, peaking in 1991:4, 2000:1, and 2009:1.

B. Variance Decomposition of Stock Returns

Following Fama and MacBeth (1973), a large literature asks to what extent characteristics explain the cross-sectional variance of stock returns. A more recent literature asks whether institutional demand explains the significant variation in stock returns that remains unexplained by characteristics (Nofsinger and Sias 1999; Gompers and Metrick 2001). We introduce a variance decomposition of stock returns that offers a precise answer to this question.

We start with the definition of log returns:

$$r_{t+1} = \log(p_{t+1} - p_t + v_{t+1}),$$

where $v_{t+1} = \log(1 + \exp(d_{t+1} - p_{t+1}))$. We then decompose the capital gain as

$$p_{t+1} - p_t = \Delta p_{t+1}(s) + \Delta p_{t+1}(x) + \Delta p_{t+1}(A) + \Delta p_{t+1}(\beta) + \Delta p_{t+1}(\epsilon),$$
where

\[ \Delta p_{t+1}(s) = g(s_{t+1}, x_t, A_t, \beta_t, \epsilon_t) - g(s_t, x_t, A_t, \beta_t, \epsilon_t), \]
\[ \Delta p_{t+1}(x) = g(s_{t+1}, x_{t+1}, A_t, \beta_t, \epsilon_t) - g(s_t, x_t, A_t, \beta_t, \epsilon_t), \]
\[ \Delta p_{t+1}(A) = g(s_{t+1}, x_{t+1}, A_{t+1}, \beta_t, \epsilon_t) - g(s_t, x_t, A_t, \beta_t, \epsilon_t), \]
\[ \Delta p_{t+1}(\beta) = g(s_{t+1}, x_{t+1}, A_t, \beta_{t+1}, \epsilon_t) - g(s_t, x_t, A_t, \beta_t, \epsilon_t), \]
\[ \Delta p_{t+1}(\epsilon) = g(s_{t+1}, x_{t+1}, A_t, \beta_{t+1}, \epsilon_{t+1}) - g(s_t, x_t, A_t, \beta_{t+1}, \epsilon_t). \]

We compute each of these counterfactual price vectors through the algorithm in Appendix B. We then decompose the cross-sectional variance of log returns as

\[
\text{Var}(r_{t+1}) = \text{Cov}(\Delta p_{t+1}(s), r_{t+1}) + \text{Cov}(\Delta p_{t+1}(x), r_{t+1}) + \text{Cov}(v_t, r_{t+1}) \\
+ \text{Cov}(\Delta p_{t+1}(A), r_{t+1}) + \text{Cov}(\Delta p_{t+1}(\beta), r_{t+1}) + \text{Cov}(\Delta p_{t+1}(\epsilon), r_{t+1}).
\] (25)

Equation (25) says that variation in asset returns must be explained by supply- or demand-side effects. The first three terms represent the supply-side effects due to changes in shares outstanding, changes in characteristics, and the dividend yield. The last three terms represent the demand-side effects due to changes in assets under management, the coefficients on characteristics, and latent demand.

Table 4 presents the variance decomposition of annual stock returns, pooled over 1981 to 2014. Because characteristics are updated in June for many stocks whose fiscal years end in December (see Section III), we use annual stock returns at the end of June to give characteristics the best chance of explaining stock returns. On the supply side, shares outstanding explain 1.4 percent, and characteristics explain 6.1 percent of the cross-sectional variance of stock returns. Dividend yield explains only 0.4 percent, which means that capital gain drives most of the cross-sectional variance of stock returns.

On the demand side, assets under management explain 28.6 percent, and the coefficients on characteristics explain 4.7 percent of the cross-sectional variance of stock returns. Latent demand is clearly the most important, explaining 58.8 percent of the cross-sectional variance of stock returns. Thus, stock returns are mostly explained by demand shocks that are unrelated to changes in observed characteristics. This finding is consistent with the fact that cross-sectional regressions of stock returns on characteristics have low explanatory power (Fama and French 2008; Asness, Frazzini, and Pedersen 2013).

Our variance decomposition establishes a new set of targets for a growing literature on asset pricing models with institutional investors (see footnote 1). A common feature of these models is that asset prices move with the wealth distribution across heterogeneous investors.
Characteristics such as dividends also matter for institutions that care about their performance relative to a benchmark. Finally, latent demand matters insofar as institutions have heterogeneous beliefs or constraints, endowment shocks, or private signals. In future work, models with institutional investors could be tested quantitatively based on our variance decomposition.

C. Stock Market Volatility in 2008

In the aftermath of the financial crisis, various regulators have expressed concerns that large investment managers could amplify volatility in bad times (Office of Financial Research 2013; Haldane 2014). The underlying intuition is that even small shocks could translate to large price movements through the sheer size of their balance sheets. Going against this intuition, however, is the fact that large institutions tend to be diversified buy-and-hold investors that hold more liquid stocks. We use the characteristics-based model to better understand the relative contributions of institutional investors and households in explaining the stock market volatility in 2008.

We modify the variance decomposition (25) as

$$\text{Var}(r_{t+1}) = \text{Cov}(\Delta p_{t+1}(s) + \Delta p_{t+1}(x) + v_{t+1}, r_{t+1}) + \sum_{i=1}^{I} \text{Cov}(\Delta p_{t+1}(A_i) + \Delta p_{t+1}(\beta_i) + \Delta p_{t+1}(\epsilon_i), r_{t+1}).$$

The first term is the total supply-side effect due to changes in shares outstanding, changes in characteristics, and the dividend yield. The second term is the sum of the demand-side effects across all investors due to changes in assets under management, the coefficients on characteristics, and latent demand. In our implementation of the variance decomposition, we first order the largest 25 institutions by their assets under management at the end of 2007, then smaller institutions, then households.

Table 5 presents the variance decomposition of stock returns in 2008. The supply-side effects explain only 5.0 percent of the cross-sectional variance of stock returns, which means that the demand-side effects explain the remainder of the variance. Barclays Bank (now part of Blackrock) is the largest institution in 2007:4, managing $699 billion. Its assets fell by 41 percent from 2007:4 to 2008:4. During this period, its contribution to the cross-sectional variance of stock returns was 0.5 percent. Summing across the largest 25 institutions, their overall contribution to the cross-sectional variance of stock returns was 5.5 percent. Smaller institutions explain 41.9 percent, and households explain 47.6 percent of the cross-sectional variance of stock returns. The three groups of investors each managed about a third of the
stock market, and their assets fell by nearly identical shares in 2008. However, the relative contribution of the largest 25 institutions to stock market volatility was much smaller than that of smaller institutions and households.

This finding is driven by two important aspects of large institutions. First, large institutions are diversified buy-and-hold investors. Figure 4 shows that the standard deviation of latent demand increased for households in 2008, but not for large institutions. Larger deviations in latent demand across stocks lead to larger deviations in prices away from fundamentals. Second, large institutions hold more liquid stocks with higher aggregate demand elasticity, for which demand shocks have less price impact.

D. Predictability of Stock Returns

To a first-order approximation, the conditional expectation of long-run capital gain is

\[ \mathbb{E}_t[p_{T} - p_t] \approx g(\mathbb{E}_t[s_t], \mathbb{E}_t[x_t], \mathbb{E}_t[A_t], \mathbb{E}_t[\beta_t], \mathbb{E}_t[\epsilon_t]) - p_t. \]

This equation says that asset returns are predictable if any of its determinants are predictable.

Based on the importance of latent demand in Table 4, we isolate mean reversion in latent demand as a potential source of predictability in stock returns. We assume that latent demand reverts to its unconditional mean of one in the long run and that all other determinants of stock returns are random walks. That is, we assume that

\[ \mathbb{E}_t[p_{T} - p_t] = g(s_t, x_t, A_t, \beta_t, 1) - p_t, \]

where we compute the counterfactual price vector through the algorithm in Appendix B. Thus, we have an estimate of long-run expected return for each stock based on mean reversion in latent demand.

To test whether our measure of long-run expected return predicts the cross section of stock returns, we run a Fama-MacBeth regression of monthly excess returns, over the 1-month T-bill rate, onto lagged characteristics (e.g., Fama and French 2008). That is, we estimate a cross-sectional regression of excess returns onto lagged characteristics, then average the estimated coefficients in the time series over our sample period from June 1980 to December 2014. To control for known sources of predictability, we control for all characteristics in the Fama-French five-factor model (i.e., log market equity, book-to-market equity, profitability, investment, and market beta) as well as momentum (i.e., 11-month return skipping the most recent month). We use data that were public in month \( t \) to predict stock returns in month.
For example, our estimate of long-run expected return in June uses the accounting data for December and 13F filing for March to leave an adequate window for reporting delays.

Table 6 shows that expected monthly returns increase by 0.24 percent per one standard deviation in long-run expected return with a highly significant t-statistic above six. Our measure of long-run expected return uncovers a new source of predictability from mean reversion in latent demand that is similar in magnitude to other characteristics that are known to predict stock returns. To verify the robustness of our results, we rerun the Fama-MacBeth regression excluding microcaps, defined as stocks whose market equity is below the 20th percentile for NYSE stocks (Fama and French 2008). We continue to find predictability with a statistically significant coefficient of 0.14 percent. The smaller coefficient, however, implies that the high returns due to mean reversion in latent demand are more prominent for smaller stocks.

VI. Extensions and Open Issues

We briefly discuss potential extensions and open issues that are beyond the scope of this paper, which we leave for future research.

A. Endogenizing Supply and the Wealth Distribution

We have assumed that shares outstanding and asset characteristics are exogenous. However, we could endogenize the supply side of the characteristics-based model, just as asset pricing in endowment economies has been extended to production economies. Once we endogenize corporate policies such as investment and capital structure, we could answer a broad set of questions at the intersection of asset pricing and corporate finance. For example, how do the portfolio decisions of institutions affect real investment at the business-cycle frequency and growth at lower frequencies?

We have also assumed that the wealth distribution is exogenous, or more primitively, that net capital flows between institutions are exogenous. By modeling how households allocate wealth across institutions (e.g., Hortaçsu and Syverson 2004; Shin 2014), we could have a more realistic demand system to better understand the relative importance of substitution across institutions versus substitution across assets within an institution.

8Recent work on incorporating institutional investors in production economies include Gertler and Karadi (2011), Adrian and Boyarchenko (2013), Brunnermeier and Sannikov (2014), and Coimbra and Rey (2015).
B. Other Holdings Data

The 13F data do not contain short positions, so we do not know short interest at the institution level. However, data on aggregate short interest for each stock are available. Therefore, we could construct an aggregate short interest sector and model it as one of the investors that enter market clearing (16). While this approach is less ideal than having short positions at the institution level, it could guide us on whether short interest matters for our empirical results.

Based on the 13F data, we can only compute aggregate household holdings as the residual of institutional holdings. In countries such as Sweden with complete household holdings data (Calvet, Campbell, and Sodini 2007), it would be possible to estimate asset demand for households at a more disaggregated level. We can then see whether households have correlated demand shocks especially in bad times, which would explain why the standard deviation of latent demand increased significantly for households during the financial crisis (see Figure 4).

In principle, our estimates of the asset demand system would improve if we could incorporate other asset classes like cash and fixed income. Unfortunately, U.S. data on institutional bond holdings are incomplete because only insurance companies and mutual funds are required to file their holdings. In addition, there is no easy way to merge the 13F data with the bond holdings data (e.g., Thomson Reuters eMAXX). Securities Holding Statistics of the European Central Bank contain the complete institutional holdings across all asset classes in the euro area (Koijen et al. 2017). These data could be used to estimate an asset demand system for both equities and fixed income in the euro area.

VII. Conclusion

Traditional asset pricing models make assumptions that are not suitable for institutional investors. First, strong assumptions about preferences, beliefs, and constraints imply asset demand with little heterogeneity across investors. Second, these models assume that investors are atomistic and have no price impact. A more recent literature allows for some heterogeneity in asset demand by modeling institutional investors explicitly (see footnote 1). However, it has not been clear how to operationalize these models to take full advantage of institutional holdings data. Our contribution is to develop an asset pricing model with rich heterogeneity in asset demand that matches institutional holdings. We also propose an instrumental variable estimator for the asset demand system to address the endogeneity of institutional demand and asset prices.

The characteristics-based model could answer a broad set of questions related to the role
of institutions in asset markets, which are difficult to answer with reduced-form regressions or event studies. For example, how do large-scale asset purchases affect asset prices through substitution effects in institutional holdings? How would regulatory reform of banks and insurance companies affect asset prices and real investment? How does the secular shift from defined-benefit to defined-contribution plans affect asset prices, as capital moves from pension funds to mutual funds and insurance companies? Which institutions drive asset pricing anomalies? We hope that our framework is useful for answering these types of questions.

The benchmark implementation of the mean-variance portfolio uses the sample mean and covariance matrix. The second implementation imposes a one-factor structure on returns, where expected returns and factor loadings are linear in characteristics (i.e., log market equity, log book equity, profitability, investment, dividends to book equity, and market beta). The third implementation approximates the portfolio weights from the second implementation as an exponential-linear function of characteristics. The sample period is monthly from January 1980 to December 2014.

Monthly excess returns, over the 1-month T-bill rate, are regressed onto lagged characteristics. This table reports the time-series mean and standard errors of the estimated coefficients. Microcaps are stocks whose market equity is below the 20th percentile for NYSE stocks. The sample period is monthly from June 1980 to December 2014.
Figure 1. First-stage $t$-statistic on the instrument for log market equity. This figure reports the minimum first-stage $t$-statistic across institutions at each date. The critical value for rejecting the null of weak instruments is 4.05 (Stock and Yogo 2005, Table 5.2). The sample period is quarterly from 1980:1 to 2014:4.
Figure 2. Coefficients on characteristics for an index fund. The characteristics-based model (10) is estimated for a hypothetical index fund, which is the same size and has the same investment universe as the Vanguard Group, at each date by GMM under moment condition (20). The quarterly sample period is from 1997:1 to 2014:4.
Figure 3. Coefficients on characteristics. The characteristics-based model (10) is estimated for each institution at each date by GMM under moment condition (20). This figure reports the cross-sectional mean of the estimated coefficients by institution type, weighted by assets under management. The quarterly sample period is from 1980:1 to 2014:4.
Figure 4. Standard deviation of latent demand. The characteristics-based model (10) is estimated for each institution at each date by GMM under moment condition (20). This figure reports the cross-sectional standard deviation of log latent demand by institution type, weighted by assets under management. The quarterly sample period is from 1980:1 to 2014:4.
Figure 5. Price impact across stocks and institutions. Price impact for each stock and institution is estimated through the diagonal elements of matrix (23), then averaged by institution type. This figure summarizes the cross-sectional distribution of price impact across stocks for the average bank, insurance company, investment advisor, mutual fund, and pension fund. The quarterly sample period is from 1980:1 to 2014:4.
Elasticity of price to latent demand

Figure 6. Aggregate price impact across stocks. Aggregate price impact for each stock is estimated through the diagonal elements of matrix (24). This figure summarizes the cross-sectional distribution of aggregate price impact across stocks. The quarterly sample period is from 1980:1 to 2014:4.
Appendix A. Proofs

Proof of Lemma 1. We write expected log utility over wealth at date $T$ as

$$E_{i,t}[^{\log}(A_{i,T})] = \log(A_{i,t}) + \sum_{s=t}^{T-1} E_{i,t}[^{\log}(A_{i,s+1}/A_{i,s})]$$

$$= \log(A_{i,t}) + \sum_{s=t}^{T-1} E_{i,t}[\log(R_{s+1}(0) + w'_{i,s}(R_{s+1} - R_{s+1}(0)))].$$ \hfill (A1)

Then the first-order condition for the Lagrangian (3) is

$$\frac{\partial L_{i,t}}{\partial w_{i,t}} = E_{i,t} \left[ \left( \frac{A_{i,t+1}}{A_{i,t}} \right)^{-1} (R_{t+1} - R_{t+1}(0)) \right] + \Lambda_{i,t} - \lambda_{i,t} 1 = 0. \hfill (A2)$$

Multiplying this equation by $1w_{i,t}'$ and rearranging, we have

$$E_{i,t} \left[ \left( \frac{A_{i,t+1}}{A_{i,t}} \right)^{-1} R_{t+1}(0) \right] = 1 + w_{i,t}'(\Lambda_{i,t} - \lambda_{i,t} 1). \hfill (A3)$$

Equation (5) follows by adding equations (A2) and (A3).

We approximate equation (A1) as

$$E_{i,t}[^{\log}(A_{i,T})] \approx \log(A_{i,t}) + \sum_{s=t}^{T-1} E_{i,t} \left[ r_{s+1}(0) + w'_{i,s}\mu_{i,s} - \frac{w'_{i,s} \Sigma_{s} w_{i,s}}{2} \right],$$

which follows from Campbell and Viceira (2002, equation 2.23):

$$\log \left( \frac{A_{i,t+1}}{A_{i,t}} \right) \approx r_{t+1}(0) + w'_{i,t} \left( r_{t+1} - r_{t+1}(0) \right) + \frac{\sigma_{i,t}^2}{2} - \frac{w'_{i,t} \Sigma_{i,t} w_{i,t}}{2}.$$\hfill (A5)

Then the first-order condition for the Lagrangian (3) is

$$\frac{\partial L_{i,t}}{\partial w_{i,t}} = \mu_{i,t} - \Sigma_{i,t} w_{i,t} + \Lambda_{i,t} - \lambda_{i,t} 1 = 0.$$

Solving for the optimal portfolio, we have

$$w_{i,t} = \Sigma_{i,t}^{-1}(\mu_{i,t} + \Lambda_{i,t} - \lambda_{i,t} 1). \hfill (A4)$$

Partition the short-sale constraints into those that are not binding versus binding as
\[ \Lambda'_{i,t} = \begin{bmatrix} \mathbf{0}' & \Lambda_{i,t}^{(2)'} \end{bmatrix} \]. We also partition the covariance matrix (4) and write its inverse as

\[ \Sigma^{-1}_{i,t} = \begin{bmatrix} \Omega^{(1)}_{i,t} & -\Sigma^{(1,1)-1}_{i,t} \Sigma^{(1,2)}_{i,t} \Omega^{(2)}_{i,t} \\ -\Sigma^{(2,2)-1}_{i,t} \Sigma^{(2,1)}_{i,t} \Omega^{(1)}_{i,t} & \Omega^{(2)}_{i,t} \end{bmatrix}, \]

where

\[ \Omega^{(1)}_{i,t} = \left( \Sigma^{(1,1)}_{i,t} - \Sigma^{(1,2)}_{i,t} \Sigma^{(2,2)-1}_{i,t} \Sigma^{(2,1)}_{i,t} \right)^{-1}, \]

\[ \Omega^{(2)}_{i,t} = \left( \Sigma^{(2,2)}_{i,t} - \Sigma^{(2,1)}_{i,t} \Sigma^{(1,1)}_{i,t} \Sigma^{(1,2)}_{i,t} \right)^{-1}. \]

Then equation (A4) becomes

\[ \begin{bmatrix} w^{(1)}_{i,t} \\ \mathbf{0} \end{bmatrix} = \begin{bmatrix} \Omega^{(1)}_{i,t} \left( \mu_{i,t}^{(1)} - \lambda_{i,t} \mathbf{1} \right) - \Sigma^{(1,1)-1}_{i,t} \Sigma^{(1,2)}_{i,t} \Omega^{(2)}_{i,t} \left( \mu_{i,t}^{(2)} + \Lambda_{i,t}^{(2)} - \lambda_{i,t} \mathbf{1} \right) \\ -\Sigma^{(2,2)-1}_{i,t} \Sigma^{(2,1)}_{i,t} \Omega^{(1)}_{i,t} \left( \mu_{i,t}^{(1)} - \lambda_{i,t} \mathbf{1} \right) + \Omega^{(2)}_{i,t} \left( \mu_{i,t}^{(2)} + \Lambda_{i,t}^{(2)} - \lambda_{i,t} \mathbf{1} \right) \end{bmatrix}. \]

Multiplying the second block by \( \Sigma^{(1,1)-1}_{i,t} \Sigma^{(1,2)}_{i,t} \) and adding the two blocks, we have

\[ w^{(1)}_{i,t} = \left( \mathbf{1} - \Sigma^{(1,1)-1}_{i,t} \Sigma^{(1,2)}_{i,t} \Sigma^{(2,2)-1}_{i,t} \Sigma^{(2,1)}_{i,t} \right) \Omega^{(1)}_{i,t} \left( \mu_{i,t}^{(1)} - \lambda_{i,t} \mathbf{1} \right) \]

\[ = \Sigma^{(1,1)-1}_{i,t} \left( \mu_{i,t}^{(1)} - \lambda_{i,t} \mathbf{1} \right). \]

The portfolio weight on the outside asset is

\[ w_{i,t}(0) = 1 - \mathbf{1}' w^{(1)}_{i,t} \]

\[ = 1 - \mathbf{1}' \Sigma^{(1,1)-1}_{i,t} \left( \mu_{i,t}^{(1)} - \lambda_{i,t} \mathbf{1} \right). \quad (A5) \]

When constraint (2) binds, we have

\[ \mathbf{1}' w^{(1)}_{i,t} = \mathbf{1}' \Sigma^{(1,1)-1}_{i,t} \left( \mu_{i,t}^{(1)} - \lambda_{i,t} \mathbf{1} \right) = 1. \]

Solving for \( \lambda_{i,t} \), we have

\[ \lambda_{i,t} = \max \left\{ \mathbf{1}' \Sigma^{(1,1)-1}_{i,t} \mu_{i,t}^{(1)} - 1, 0 \right\} \quad (A6) \]

**Proof of Proposition 1.** Under Assumption 1, let \( \mu_{i,t}^{(1)} = y_{i,t}' \Phi_{i,t} + \phi_{i,t} \mathbf{1} \) be the vector of expected excess returns on assets for which the short-sale constraints are not binding.
Similarly, let $\Gamma^{(1)}_{i,t} = y^{(1)}_{i,t} \Psi_{i,t} + \psi_{i,t} \mathbf{1}$ be the vector of factor loadings on those assets. The vector of optimal portfolio weights is

$$w^{(1)}_{i,t} = \left( \frac{1}{w_{i,t}(0)} \left( \Gamma^{(1)}_{i,t} \Gamma^{(1)\prime}_{i,t} + \gamma_{i,t} \mathbf{I} \right)^{-1} \left( \mu^{(1)}_{i,t} - \lambda_{i,t} \mathbf{1} \right) \Gamma^{(1)\prime}_{i,t} \right)^{-1} \left( \mu^{(1)}_{i,t} - \lambda_{i,t} \mathbf{1} \right)$$

$$= y^{(1)}_{i,t} \Pi_{i,t} + \pi_{i,t} \mathbf{1},$$

where the second line follows from the Woodbury matrix identity. QED

Proof of Corollary 1. Let $\widehat{\beta}'_{i,t} = \left[ \beta'_{i,t} \ 1 \right]$. We restrict the coefficients on characteristics in equation (8) so that

$$\Pi_{i,t} = \begin{bmatrix} \frac{1}{2} \text{vec} \left( \widehat{\beta}_{i,t} \widehat{\beta}'_{i,t} \right) \\ \vdots \end{bmatrix}$$

and $\pi_{i,t} = 1$. Equation (8) then becomes

$$w_{i,t}(n) = 1 + y_{i,t}(n) \Pi_{i,t}$$

$$= 1 + \widehat{x}_{i,t}(n) \widehat{\beta}_{i,t} + \frac{\text{vec}(\widehat{x}_{i,t}(n) \widehat{x}_{i,t}(n)^\prime) \text{vec} \left( \widehat{\beta}_{i,t} \widehat{\beta}'_{i,t} \right)}{2!} \cdots$$

$$= \sum_{m=0}^{M} \frac{(\widehat{x}_{i,t}(n) \widehat{\beta}_{i,t})^m}{m!} \rightarrow \exp \left\{ \widehat{x}_{i,t}(n) \widehat{\beta}_{i,t} \right\}$$

in the limit as $M \rightarrow \infty$. QED

Proof of Proposition 2. The function $f(p)$ is continuously differentiable because $w_i(p)$ is continuously differentiable. Let $B_- = \{ i | \beta_{0,i} \leq 0 \}$ be the set of investors for whom the coefficient on log market equity is negative, and let $B_+ = \{ i | 0 < \beta_{0,i} < 1 \}$ be the complement.
set of investors. Consider the characteristic equation for the matrix \( I - \partial f / \partial p' \):

\[
\det \left( (1 - c)I - \frac{\partial f}{\partial p'} \right) = \det(H^{-1}) \det \left( (1 - c)H - \sum_{i=1}^{I} A_i \frac{\partial w_i}{\partial p'} \right)
\]

\[
= \det(H^{-1}) \det \left( \sum_{i \in B_-} A_i (1 - c)\text{diag}(w_i) - \sum_{i \in B_-} A_i \beta_{0,i} G_i \right)
\]

\[
+ \sum_{i \in B_+} A_i (1 - c - \beta_{0,i})\text{diag}(w_i) + \sum_{i \in B_+} A_i \beta_{0,i} w_i w_i' \right) = 0.
\]

Note that \( \det(H^{-1}) > 0 \) because \( H^{-1} \) is symmetric positive definite. If \( c < 1 - \max_{i \in \{1, \ldots, I\}} \beta_{0,i} \), the second determinant on the right side is also positive because the expression inside parentheses is a sum of four symmetric positive definite matrices. By contradiction, every solution of the characteristic equation must satisfy \( c \geq 1 - \max_{i \in \{1, \ldots, I\}} \beta_{0,i} \). That is, the minimum eigenvalue of \( I - \partial f / \partial p' \) must be greater than \( 1 - \max_{i \in \{1, \ldots, I\}} \beta_{0,i} \).

The norm of the inverse of a positive definite matrix is equal to the inverse of its minimum eigenvalue. This implies that

\[
\left\| \left( I - \frac{\partial f}{\partial p'} \right)^{-1} \right\| \leq \frac{1}{1 - \max_{i \in \{1, \ldots, I\}} \beta_{0,i}}.
\]

By the Hadamard theorem (Granas and Dugundji 2013, p. 83), this uniform bound is sufficient for the function \( p - f(p) \) to be globally invertible. Therefore, \( f(p) \) has a unique fixed point.

QED

Appendix B. Algorithm for Computing the Equilibrium

This appendix describes an efficient algorithm for computing the equilibrium price vector in any counterfactual experiment. Starting with any price vector \( p_m \), the Newton’s method would update the price vector through

\[
p_{m+1} = p_m + \left( I - \frac{\partial f(p_m)}{\partial p'} \right)^{-1} (f(p_m) - p_m).
\]
For our application, this approach would be computationally slow because the Jacobian has a large dimension. Therefore, we approximate the Jacobian with only its diagonal elements:

\[
\frac{\partial f(p_m)}{\partial p} \approx \text{diag} \left( \min \left\{ \frac{\partial f(p_m)}{\partial p(n)}, 0 \right\} \right)
\]

\[
= \text{diag} \left( \min \left\{ \frac{\sum_{i=1}^{I} A_i \beta_0 \ell_i}{\sum_{i=1}^{I} A_i \ell_i(n, p_m)}, 0 \right\} \right),
\]

where the minimum ensures that the elements are bounded away from one. In the empirical applications of this paper, we have found that this algorithm is fast and reliable, converging in fewer than 100 steps in most cases.

### Appendix C. Institution Types

To group institutions into six types, we use the type codes from the Thomson Reuters Institutional Holdings Database (s34 file) and manager numbers from the Mutual Fund Holdings Database (s12 file). Thomson Reuters assigns each manager to a type code: 1) banks, 2) insurance companies, 3) investment companies, 4) investment advisors, and 5) other managers (i.e., pension funds, endowments, and foundations). Unfortunately, there is a known error in the type codes since December 1998 (Wharton Research Data Services 2008). We correct the type codes through the following steps.

1. For managers that existed prior to December 1998, we replace the incorrect type code after December 1998 with the correct one before that date.

2. We reassign type code 5 to 1 when the manager is unambiguously a bank based on its name. Similarly, we reassign type code 5 to 2 when the manager is unambiguously an insurance company.

3. In cases where the type code for a manager changes, we use the most recent type code so that a manager has a unique type code throughout the sample.

4. We construct a database of investment advisors based on the historical archives of Securities and Exchange Commission Form ADV since June 2006. We use the bigram algorithm to match manager names to business or legal names in the investment advisor database. We reassign type codes 3 and 5 to 4 when there is a valid match.

Using the corrected type codes, we assign type code 1 to banks and type code 2 to insurance companies. We assign type codes 3 and 4 to mutual funds if the manager number
matches a record in the Mutual Fund Holdings Database. Otherwise, we assign type codes 3 and 4 to investment advisors. Among managers with type code 5, we identify pension funds based on a list of top 300 pension funds (Towers Watson 2015).

Table C1 summarizes the 13F institutions in our sample by type from 1980 to 2014. We note that these statistics do not necessarily match the U.S. national accounts (Board of Governors of the Federal Reserve System 2015). The reason is that the 13F statements are based on who exercises investment discretion over the assets, whereas the national accounts are based on who ultimately owns the assets. For example, the assets of a pension fund whose portfolio is managed by an investment advisor would be accounted under investment advisors according to the 13F statements but pension funds in the national accounts.

This table reports the time-series mean of each summary statistic within the given period, based on Securities and Exchange Commission Form 13F. The sample period is quarterly from 1980:1 to 2014:4.
Appendix D. Examples of Investment mandates

We use three examples from the mutual fund industry to illustrate the use of investment mandates. The examples are chosen to represent different management styles (passive versus active) and fund sizes to illustrate the prevalence of investment mandates throughout the industry.

1. The Vanguard 500 Index Fund (ticker VFINX) is a passive index fund that tracks the S&P 500 index. Its total net assets were $329.30 billion on July 25, 2017. The prospectus (April 27, 2017) states the principal investment strategy as:

   The Fund attempts to replicate the target index by investing all, or substantially all, of its assets in the stocks that make up the Index, holding each stock in approximately the same proportion as its weighting in the Index.

2. State Street Global Advisors offer Select Sector SPDRs (tickers XLY, XLP, XLE, XLF, XLV, XLI, XLB, XLRE, XLK, and XLU), which is a group of passive exchange traded funds that track industry indices (i.e., consumer discretionary, consumer staples, energy, financial, health care, industrial, materials, real estate, technology, and utilities). The total net assets for this group of exchange traded funds were $120.72 billion on July 25, 2017. The prospectus (January 31, 2017) states the principal investment strategy as:

   In seeking to track the performance of the Index, the Fund employs a replication strategy, which means that the Fund typically invests in substantially all of the securities represented in the Index in approximately the same proportions as the Index.

3. Transamerica Dividend Focused Fund (ticker TDFAX) is an active mutual fund that “seeks total return gained from the combination of dividend yield, growth of dividends and capital appreciation.” Its total net assets were $95.52 million on July 25, 2017. The prospectus (January 31, 2017) states the principal investment strategy as:

   The fund’s sub-adviser, Barrow, Hanley, Mewhinney & Strauss, LLC (the “sub-adviser”), deploys an active strategy that seeks large and middle capitalization U.S.-listed stocks, including American Depositary Receipts, which make up a portfolio that generally exhibits the following value characteristics: price/earnings and price/book ratios at or below the market (S&P 500).
and dividend yields at or above the market. In addition, the sub-adviser considers stocks for the fund that not only currently pay a dividend, but also have a consecutive 25-year history of paying cash dividends. The sub-adviser also seeks stocks that have long established histories of dividend increases in an effort to ensure that the growth of the dividend stream of the fund’s holdings will be greater than that of the market as a whole. If a stock held in the fund omits its dividend, the fund is not required to immediately sell the stock, but the fund will not purchase any stock that does not have a 25-year record of paying cash dividends.

**Appendix E. Alternative Estimators**

The estimation sample in our benchmark estimates of the characteristics-based model (10) includes zero holdings (i.e., \( \epsilon_i(n) = 0 \)). If we were to limit the estimation sample to strictly positive holdings (i.e., \( \epsilon_i(n) > 0 \)), we could take the logarithm of equation (10) and obtain a linear specification:

\[
\log \left( \frac{w_i(n)}{w_i(0)} \right) = \beta_{0,i} \text{me}(n) + \sum_{k=1}^{K-1} \beta_{k,i} x_k(n) + \beta_{K,i} + \log(\epsilon_i(n)).
\]

(E1)

This specification is inefficient and potentially biased because the fact that an investor does not hold certain assets could be useful for identifying the coefficients on characteristics.\(^9\)

We examine how our benchmark estimates compare with those based on two alternative estimators. The first alternative is estimation of the linear model (E1) by restricted least squares (imposing \( \beta_{0,i} < 1 \)) under the moment condition

\[
\mathbb{E}[\log(\epsilon_i(n))|\text{me}(n), x(n)] = 0.
\]

The second alternative is estimation of the linear model (E1) by GMM under the moment condition

\[
\mathbb{E}[\log(\epsilon_i(n))|\widehat{\text{me}}_i(n), x(n)] = 0.
\]

The first alternative shows the importance of the instrument, while the second alternative shows the importance of estimating in levels with zero holdings.

\(^9\)Santos Silva and Tenreyro (2006) highlight an analogous issue in international trade that estimates of the gravity equation depend on whether they are estimated in levels (with observations of zero bilateral trade) or logarithms.
The upper panel of Figure E1 is a scatter plot of the coefficient on log market equity estimated by restricted least squares versus linear GMM. We fit a linear regression line through the scatter points, both equal-weighted and value-weighted by assets under management. On average, the least squares estimates are higher than the linear GMM estimates, especially for larger institutions. This finding is consistent with the hypothesis that latent demand and asset prices are jointly endogenous, which leads to a positive bias in the least squares estimates.

The lower panel of Figure E1 is a scatter plot of the coefficient on log market equity estimated by linear GMM versus nonlinear GMM. We again fit a linear regression line through the scatter points. The value-weighted regression line is close to the 45-degree line, which means that the two alternative estimates are similar for larger institutions. However, the equal-weighted regression line is mostly above the 45-degree line, which means that the linear GMM estimates are on average higher than the nonlinear GMM estimates. For smaller institutions, the coefficient on log market equity is lower when we estimate in levels with zero holdings.
Figure E1. Comparison of the coefficient on log market equity. The upper panel is a scatter plot of the coefficient on log market equity estimated by restricted least squares versus linear GMM. The lower panel is a scatter plot of the coefficient on log market equity estimated by linear versus nonlinear GMM. The quarterly sample period is from 1980:2 to 2014:2.
