

Uniform Pricing in US Retail Chains

October 18, 2017

Abstract

We show that most US grocery, drug, and mass-merchandise chains charge nearly-uniform prices across stores, despite wide variation in consumer demographics and the level of competition. Estimating a model of consumer demand reveals substantial within-chain variation in price elasticities and suggests that the average chain sacrifices seven percent of profits relative to a benchmark of flexible prices. In contrast, differences in average prices between chains broadly conform to the predictions of the model. As possible explanations for near-uniform pricing, we discuss advertising, tacit collusion, fairness concerns, and managerial fixed costs, and find the most support for the last explanation. We show that the uniform pricing we document significantly increases the prices paid by poorer households relative to the rich, likely dampens the overall response of prices to local economic shocks, and may also shift the incidence of intra-national trade costs.

1 Introduction

Recent research across several domains highlights the importance of retail price adjustment to local shocks. Beraja, Hurst, and Ospina (2016) and Stroebel and Vavra (2015) find that local retail prices increase in response to positive shocks to consumer demand, and argue that such price responses have important implications for understanding business cycles. Atkin and Donaldson (2015) show that retail prices are higher in more remote areas due to intra-national trade costs, and that consumers in these areas benefit less from globalization as a result. Jaravel (2016) shows that prices have fallen more in high-income areas, possibly due to higher rates of product innovation, and that this has significantly exacerbated rising inequality. In interpreting the data, authors in these areas typically start from models in which local prices are set optimally in response to local costs and demand.

In this paper, we show that most large US grocery, drugstore, and mass-merchandise chains in fact set uniform or nearly-uniform prices across their stores. This fact echoes uniform pricing “puzzles” in markets such as soft drinks (McMillan, 2007), movie tickets (Orbach and Einav, 2007), rental cars (Cho and Rust, 2010), and online music (Shiller and Waldfogel, 2011), but is distinct in that prices are held fixed across separate markets, rather than across multiple goods sold in a single market. We show that limiting price discrimination in this way costs firms significant short-term profits. We then show that the result of nearly-uniform pricing is a significant dampening of price adjustment, and that this has important implications for the pass-through of local shocks, the incidence of trade costs, and the extent of inequality.

Our analysis is based on store-level scanner data for 9,415 grocery stores, 9,977 drugstores, and 3,288 mass-merchandise stores from the Nielsen-Kilts retail panel. In our baseline results, we focus on prices of ten widely available items, and we use the standard price measure in these data, which is defined to be the ratio of weekly revenue to weekly units sold.

Our first set of results documents the extent of uniform pricing. While we observe no cases in which the measured price is the same for all products across stores, the variation in prices within chains is small in absolute terms and far smaller than variation between stores in different chains. This is true despite the fact that consumer demographics and levels of competition vary significantly within chain: consumer income per capita ranges from \$22,700 at the average 10th-percentile store to \$40,900 at the average 90th-percentile store, and the number of competing stores within 10km varies from 0.6 at the 10th-percentile store to 8.3 at the 90th-percentile store.¹ Prices are highly similar within chain even if we focus on store pairs that face very different income levels, or that are in geographically separated markets. We can also look directly at the relationship of price to consumer income. Within chain, prices increase by 0.72 percent (s.e. 0.12) for each \$10,000 increase in the income of local customers. Between chains—that is, comparing chain average prices to chain

¹The within-chain heterogeneity is only slightly smaller than the cross-sectional heterogeneity across stores, with income in the 10th-percentile store of \$19,300 and income in the 90th-percentile store at \$41,700.

average income—they increase by 4.48 percent (s.e. 1.01).² Another way of looking at the same fact is to regress a store’s log price on (i) the income of consumers in its own market and (ii) the average income of consumers in its chain; the coefficient on the former is an order of magnitude smaller than the coefficient on the latter (0.004 vs. 0.040). All of these results remain similar for various alternative products, including store brands, lower-selling items, and high-priced items.

Next, we show that the way prices are measured in the Nielsen data means that the degree of uniform pricing is likely even greater than these results would suggest. If not all consumers pay the same price within a given week, the weekly ratio of revenue to units sold will yield the quantity-weighted average price. This ratio can vary across stores not only because of variation in the prices but also because of variation in the quantity weights. In particular, we expect stores facing more elastic demand (e.g., lower income) to sell a larger share of units at relatively low prices, leading the weekly price measure to be lower in such stores, even if posted prices do not vary at all. Thus, the aggregation to weekly average prices can lead not only to excess variance in measured prices, but also to apparent correlation between measured prices and income.³

To assess the importance of this compositional bias, we turn to more detailed data from a major grocer studied in Gopinath et al. (2011) that allows us to see posted non-sale prices directly. These data suggest two reasons that consumers within a given week pay different prices. First, Nielsen’s weeks run from Sunday to Saturday while this retailer typically changes prices mid-week. Second, consumers with loyalty cards pay lower prices than those without loyalty cards.⁴ When we use the standard Nielsen price measure, this chain looks similar to other grocery chains in having a small but clearly non-zero price-income gradient.⁵ When we adjust for the compositional biases and look directly at the posted prices, however, this relationship completely disappears.

For the large majority of the 73 chains in our data measured prices vary very little across stores, and we suspect based on our analysis of the major grocer that their posted prices are in fact essentially uniform. For 11 grocery chains as well as the two major drug chains, prices vary at the level of large geographic zones, but vary much less within them.

Our second set of results uses a simple constant-elasticity model of demand to assess the extent to which uniform pricing represents a deviation from (short-run) optimal prices. The model fits the data well, with an observed relationship between weekly log quantity and weekly log price very close to linear. The store-level estimate of elasticity is both statistically quite precise and closely predicted

²The between-chain comparison includes just food stores, given that there are too few drug or mass merchandise chains for a meaningful between-chain comparison.

³The importance of the distinction between posted prices and average prices paid has been previously emphasized by Chevalier and Kashyap (2015) and Coibion, Gorodnichenko, and Hong (2015). They point out that average prices paid at the annual or market level may be responsive to macroeconomic shocks even when posted prices are constant. To the best of our knowledge, we are the first to emphasize that this same force affects the weekly average prices commonly available in scanner data. Indeed, both Chevalier and Kashyap (2015) and Coibion, Gorodnichenko, and Hong (2015) treat the weekly average price as equivalent to the posted price.

⁴Einav, Leibtag, and Nevo (2010) discuss further measurement error due to loyalty cards in Nielsen data.

⁵Give that this chain does zone pricing at the state level, we estimate the pricing gradient with state fixed effects.

by store-level measures of demographics and competition. Estimated elasticities vary widely within chains, ranging from -2.28 at the average 10th percentile to -2.98 at the average 90th percentile in food stores, -1.94 to -2.65 in drugstores, and -2.92 to -3.67 in mass-merchandise stores. Our model implies that the ratio of the optimal price to marginal cost for a store with elasticity η_s is $\eta_s / (1 + \eta_s)$. Assuming no variation in marginal costs across stores, prices at stores with elasticities in the 90th percentile should be 18 percent higher than stores with elasticities in the 10th percentile in food stores, 29 percent higher in drugstores, and 11 percent higher in mass-merchandise stores; observed prices are on average only 0.4 percent higher in food stores, 0.8 percent higher in drugstores, and 0.4 percent higher in mass-merchandise stores.⁶ To formally test the model’s predictions, we regress log prices on the term $\log [\eta_s / (1 + \eta_s)]$, instrumenting for this term with store income. This yields a between-chain coefficient for grocery chains of 0.94 (s.e. 0.22), very close to the value of 1 that the model would predict. The within-chain coefficient is an order of magnitude smaller, at 0.09 (s.e. 0.03), and the compositional issues discussed above suggest this is likely an over-estimate.

The model allows us to quantify the loss of profits from uniform pricing. The loss is highest for stores in high-income areas, where prices would be substantially higher under optimal pricing. We estimate that the average chain could increase profits by 6.9 percent under flexible pricing.

We consider a number of potential threats to the validity of our model. First, our model abstracts from variation in marginal costs across stores. Stroebel and Vavra (2015) present a range of evidence suggesting that such variation is likely to be small, and this is supported by our analysis of the major grocer data. To the extent that marginal costs do vary, we would expect them to be positively correlated with income, meaning that our model if anything understates the gap between observed and optimal prices. Second, our baseline estimates assume that short-run week-to-week elasticities are equal to long-run elasticities. The long-run elasticities relevant to the store’s problem could in fact be smaller (due to consumer stockpiling as in Hendel and Nevo, 2006) or larger (due to search). We repeat our analysis using prices and quantities aggregated to the quarterly level and find that the broad patterns are unchanged, and also show that the results are similar for storable and non-storable products. Third, our main analysis treats demand as separable across products. Cross-product substitution could lead us to over-state the relevant elasticities as consumers substitute among products, or under-state them as consumers substitute on the store-choice margin as in Thommasen et al. (2017). To partially address this concern we show that estimated elasticities are similar when we aggregate prices and quantities to the product category level. Finally, prices and promotions are often determined jointly by retailers and manufacturers (Anderson et al., 2017). The fact that our results are similar for store brands suggests that constraints imposed by manufacturers are unlikely to be a key driver of our results.

⁶For observed prices, we calculate this by selecting stores that have elasticities within .05 of the 10th and 90th elasticity percentiles in each chain. We compute the within-chain difference first (i.e. the within-chain difference in average prices for stores near the 90th percentile and stores near the 10th percentile) and then take the average difference, weighting each retailer equally.

The third section of our analysis considers potential explanations for uniform pricing. We argue that neither menu costs (Mankiw, 1985) nor price advertising provide plausible explanations. We see softening price competition and fairness concerns as potentially more plausible, but to the extent we are able to test them with our data we find limited support. The explanation we find the most support for is managerial decision-making costs (Bloom and Van Reenen, 2007).⁷ Implementing more flexible pricing policies may impose chain-level fixed costs such as up-front managerial effort in pricing design, or a cost for inertial managers to deviate from the traditional pricing approach in the industry. Two pieces of evidence are consistent with such fixed costs. First, chains with more stores, with higher average store revenue, or facing more variable consumer income levels are more likely to deviate from uniform pricing. Second, among the drug and mass merchandise chains (though not for the food chains) the extent of uniform pricing has decreased over time, consistent with improvements in technology reducing managerial fixed costs.

In the final section of the paper, we turn to the implications of uniform pricing for the broader economy. We first show that uniform pricing exacerbates inequality, increasing prices posted to consumers in the poorest decile of zip codes by 8 percent relative to the prices posted to consumers in the richest decile. We then show that uniform pricing is likely to substantially dampen the response of prices to local demand shocks. This significantly shifts the incidence of these shocks – for example, exacerbating the negative effects of the great recession on markets with larger declines in housing values. Finally, we show that uniform pricing may change the incidence of intra-national trade costs, benefiting more remote areas that otherwise would pay significantly higher prices, and that it can also bias estimates of these costs that use spatial price gaps as a key input. In several of these cases, we also note that the standard practice of treating average prices paid at weekly or greater time horizons as equivalent to posted prices can also be a source of bias in the results.

We are not the first to document uniform pricing policies in retailing.⁸ Prior work has noted uniform pricing by European supermarkets and other major European retailers.⁹ Early studies of the Dominicks chain in the Chicago market showed that Dominicks varied prices between pricing zones but kept prices constant within zone, and the same is true for the widely-studied major US grocer from Gopinath et al. (2011).¹⁰ The more comprehensive Nielsen data set shows that, while a

⁷A different version of this explanation is that managers are simply unaware of the income differences across their stores, or that they lack the information to recognize its implications for optimal prices. This seems unlikely to us.

⁸Our discussion of the literature focuses on private retail firms. Miravete, Seim, and Thurk (2014) offer a related analysis of the implications of a uniform markup regulation applied to government-run liquor stores in Pennsylvania. Their work parallels ours in estimating variation of demand elasticities and considering the distributional implications of uniform pricing.

⁹Reports from UK regulators show that roughly half of UK supermarket chains charge uniform prices across stores (Competition Commission, 2003, 2005; Dobson and Waterson, 2008) as do the main UK electronics retailers (MMC, 1997a,b). Cavallo, Nieman, and Rigobon (2014) show that Apple, IKEA, H&M, and Zara charge nearly uniform prices across the Euro zone in their online stores, though they charge different (real) prices across countries with different currencies. Eizenberg, Lach, and Yiftach (2017) study price variation across supermarkets in Jerusalem.

¹⁰See Hoch et al. (1995), Montgomery (1997), and Chintagunta, Dubé, and Singh (2003). It may not be a coincidence that the chains which have been most likely to partner with researchers are also the ones that implement the most sophisticated pricing policies. The focus of research on these chains may also explain why the full extent of uniform

minority of US food chains indeed does zone pricing, near-uniform pricing is the industry norm.

Two recent papers are particularly related. Adams and Williams (2017) show that the Home Depot and Lowe’s US hardware chains use a zone pricing strategy, with different degrees of price flexibility for different products. They estimate a structural model of demand and oligopoly pricing for a single product, drywall, and use it to evaluate how profits would change under more flexible pricing for this product. Contemporaneous work by Hitsch, Hortacısu, and Lin (2017) uses the same Nielsen data we do to decompose price variation for close to fifty thousand products. Though their main focus is separating the roles of regular price variation and promotions, they also note that prices vary more between chains than within chains, and they also estimate elasticities for a large set of stores. Our paper differs from prior work in more sharply characterizing the extent of uniform pricing, in comparing observed pricing to an optimal benchmark, and in addressing broader economic implications.

More broadly, our paper relates to a large body of work on the extent and implications of local retail price responses to economic shocks or incentives. Examples beyond those cited above include Broda and Weinstein (2008), Gopinath et al. (2011), Coibion, Gorodnichenko, and Hong (2015), Fitzgerald and Nicolini (2014), Handbury and Weinstein (2015), and Kaplan and Menzio (2015). Our work also speaks to the literature tracing out the implications of retail firms’ price setting for macroeconomic outcomes, including influential early work using scanner data by Bils and Klenow (2004) and Nakamura and Steinsson (2008) and recent contributions such as Anderson et al. (2017).

Finally, our paper relates to work in behavioral industrial organization (for a review, see Heidhues and Koszegi, 2018). Most of the work in this area has focused on firms optimally responding to behavioral consumers (DellaVigna and Malmendier, 2004; Gabaix and Laibson, 2006). Our paper is part of a smaller literature which considers instead *behavioral firms*, that is, cases in which firms deviate from simple benchmarks of profit maximization (Romer, 2006; Bloom and Van Reenen, 2007; Hortacısu and Puller, 2008; Goldfarb and Xiao, 2011; Massey and Thaler, 2013; Hanna, Mullainathan, and Schwartzstein, 2014; Hortacısu et al., 2017; Ellison, Snyder, and Zhang, 2017).

2 Data

Our primary data sources are the Nielsen Retail Scanner (RMS) and Consumer Panel (Homescan, HMS) data provided by the Kilts Center at the University of Chicago.¹¹ The retailer scanner panel records the average weekly revenue and quantity sold for over 35,000 stores in the US over the 2006-2014 period, covering about a million different unique products (UPCs). We use this data set to extract the information on weekly price and quantity. We also use some information from the consumer panel which is based on following the purchase of 60,000+ consumers across different

pricing has been under-appreciated.

¹¹<https://research.chicagobooth.edu/kilts/marketing-databases/nielsen>

stores. We present the main information in this Data section, with additional detail in the Appendix.

Stores. We focus the analysis on three store types, or channels: food (i.e., grocery), drug, and mass-merchandise. Table 1, Panel A shows that the initial Nielsen sample includes 38,539 stores for a total average yearly revenue (as recorded in the RMS data) of \$224 billion.¹²

We define a chain to be a unique combination of two identifiers in the Nielsen data: `parent_code` and `retailer_code`. The former generally indicates the company that owns a store and the latter indicates the chain itself¹³. Nielsen does not disclose the names of the chains in the data, but a general example would be the Albertson’s LLC parent company which owns chains including Albertson’s, Shaw’s, and Jewel-Osco. Sometimes, a single `retailer_code` appears under multiple `parent_codes`, possibly for reasons related to mergers. We introduce additional restrictions detailed below to exclude cases like these where chain identity is unclear.

We first introduce set of sample restrictions at the store level. We exclude stores that switch chains over time¹⁴, stores that are in the sample for fewer than two years¹⁵, and stores without any consumer purchases in the Homescan data. This reduces the sample to 22,985 stores in 113 chains.

We next introduce restrictions at the chain level. We require that the chains are present in the sample for at least 8 of the 9 years; this eliminates a few chains with typically only a small number of stores each with inconsistent presence in the data. Next, we resolve cases where the mapping of stores to chains is not sufficiently clear. A first concern occurs when the same `retailer_code` identifier appears for stores with different `parent_codes`. It is unclear whether the use of the same `retailer_code` in this case indicates that these stores belong to one chain, or perhaps they belong to a subchain that changed owner, or something else. Thus, for each `retailer_code`, we only keep the `parent_code` associated with the majority of its stores, and then further exclude cases in which this `retailer_code`-`parent_code` combination accounts for less than 80% of the stores with a given `retailer_code`. A second concern is for chains in which a number of stores switch chain, given that this may indicate a change in ownership of the entire chain. We thus exclude chains in which 60% or more of stores belonging to the `retailer_code`-`parent_code` change either `parent_code` or `retailer_code` in our sample.

To define the demographics of the stores, we use the HMS data, which includes all shopping trips for the consumers in the panel. The median store has 21 Nielsen consumers ever purchasing at the store, for a total of 502 trips (Panel B of Table 1). We use variables like income and education from the 2008-2012 5-year ACS for the 5-digit zip code of residence of the consumers shopping in each store, and then compute the weighted average across the consumers, weighting by the number of

¹²This number omits revenue from products like most produce or prescription drugs that are not in the data.

¹³However, some parent companies report their data to Nielsen in a decentralized manner representing each of their retail chains, so we do not observe all ownership relationships.

¹⁴In some cases, we can validate the ownership change with significant observed changes in prices in the switching stores. However, some of the pricing changes occur up to 2 years in advance, or 2 years after, the change, suggesting a possible inaccurate record of the timing of ownership changes. Hence our conservative rule of excluding such switches.

¹⁵This sample restriction is especially important for our estimation of price elasticities, since our elasticity estimates include controls for 52 week-of-year indicators, requiring multiple observations per week-of-year.

trips that they take to the store.¹⁶ We let Y_s denote this measure of income for store s .

Table 1 provides summary statistics for our main sample. Panel A summarizes the sample restrictions, which result in a final sample of 22,680 stores from 73 chains, covering a total of \$191 billion of average yearly revenue. These include 9,415 stores from 64 food store chains (\$136 billion average yearly revenue), 9,977 stores from 4 drugstore chains (\$21 billion), and 3,288 stores from 5 mass-merchandise chains (\$34 billion). Panel B summarizes these stores’ demographics. The median store has an average per-capita income of \$26,900, with sizable variation across stores; for example, the 75th percentile is at \$33,750. Panel C-E provide chain-level summary statistics. The median food chain (Panel C of Table 1) has 66 stores, and has locations in 4 DMAs and 2.5 states. Drugstore and mass-merchandise chains (Panels D and E) are significantly larger and span more states, with the vast majority of stores in both cases belonging to 2 chains. Given this high concentration, our between-chain analyses below are limited to food chains.

Our store sample covers the entire continental US (see map in Appendix Figure 1), with a number of stores and chains that is fairly constant between 2007 and 2013 (Online Appendix Table 1).

Products. We focus most of our analysis on a set of products that are both frequently sold and widely available. This guarantees clean comparisons both within and between chains, and avoids the problem that the price measure is missing in weeks with zero sales. This is an issue especially because the price is not missing at random—a week with no purchases is less likely to occur when a product is on a price reduction—thus introducing a potential bias in the price measure.

For food stores, we focus on one UPC from each of 10 product categories (“modules”): canned soup, cat food, chocolate, coffee, cookies, soda, bleach, toilet paper, yogurt and orange juice.¹⁷ We define the first eight to be storable products and the last two to be non-storable products. These modules together account for an average yearly revenue of \$13.7 billion across the 9,415 stores in our food store sample, or 10.1 percent of total revenue. For drug and mass merchandise stores, we focus on the subset of these modules in which some UPC is available in at least 90 percent of stores: soda and chocolate for drug stores, and soda, chocolate, cookies, bleach, and toilet paper for mass merchandise. Within each module, we choose a specific UPC to maximize sales and availability across our sample of stores. In most cases, these UPCs remain the same across years; in all cases, the UPC is the same across stores within a channel and year. Examples of products in our sample (Table 2) include a 12-can package of Coca-Cola, a single 14.5 oz can of Campbell’s Cream of Mushroom soup, and a 59 oz. bottle of pulp-free Simply Orange juice.

In our robustness analysis, we consider larger sets of products. To avoid availability issues, we construct these larger product samples only for food stores. They include less commonly sold items

¹⁶This demographic information is more accurate than the one that can be computed directly from the location of the store in the RMS data, since in this dataset the most precise geographic location given is the county or 3-digit zip code. Weighting by total dollar amount spent or using the unweighted average does not meaningfully change our imputed demographics.

¹⁷These modules have a large overlap with ones used in previous analyses, e.g., Hoch et al. (1995)

(the 20th highest-availability product across chains for each module), high-quality items (chosen to have a high-unit-price) product, the top-selling generic product within each chain, a subset of generic products comparable across chains, and a large basket of products we use to construct module-level price and quantity indices.¹⁸

To define the module-level baskets, we include all UPCs in a module such that the average share of weeks with non-zero sales for that UPC is at least 95 percent, where the average is taken across stores.¹⁹ For some modules such as soda and orange juice, products meeting this criterion cover 50-60 percent of the total module revenue, while for other modules like chocolate or coffee, they cover just 15-20 percent (see Online Appendix Table 1, Panel B). Summing over the 10 modules, these products cover an average annual revenue of \$6bn.

Prices. As is standard in the literature, we define the price P_{sjt} in store s of product j in week t to be the ratio of the weekly revenue to weekly units sold. The price is not defined if no units are sold in a UPC-store-week. We let p_{sjt} denote the standardized log price, defined as $\log(P_{sjt})$ minus the average of $\log(P_{sjt})$ across stores and weeks within each year and store format. To define the average log price of store s , \bar{p}_s , we first average p_{sjt} within years to produce a mean \bar{p}_{sjy} ; we then define \bar{p}_s to be the simple average of \bar{p}_{sjy} across products j and years y .

Table 2 summarizes prices and availability for the products in our main sample. The average price varies from \$0.49 for cat food in food stores to \$8.70 for toilet paper in mass merchandise stores (Column 3). The products have at least one recorded sale in the large majority of store-weeks, for example in 99.7% of store-week-UPC observations for chocolate in food stores (Column 4). Cat food, coffee, and toilet paper have somewhat lower availability in food stores, as do most of the products sold in drugstores and mass-merchandise stores, but are still in the range around or above 95%. We also compute the average yearly revenue per store that these products generate, with the highest number associated with the soda product in food stores, \$34,100.

To compute the module-level price and quantity index for store s we start from the weekly log price p_{sjt} and weekly log units sold q_{sjt} , then average across all products j included in the basket for that module-chain-year. As weights, we use the total quantity sold for product j in a chain-year. If a product j has no sales in a particular store s and week t , product j is omitted for that store-week cell, and the other weights are scaled up accordingly.²⁰

Major Grocer Data. We use supplemental scanner data from a single major grocer (parent_code) studied in Gopinath et al. (2011). These data contain the same variables as the Nielsen data, plus gross revenue (defined to be the total revenue had all transactions occurred at the non-

¹⁸See Appendix Section A.1.4 for more details

¹⁹We omit weeks from this calculation in which the store has zero recorded sales in all ten modules.

²⁰We use the same weights for the price variable and the quantity variable so that, under the assumption that all products within a module have a constant-elasticity demand with the same elasticity η , we can recover the elasticity η regressing the index quantity on the index price. We use quantity weights so that our price index resembles a geometric modified Laspeyres Index, similar for example to Beraja, Hurst, and Ospina (2016) and to how the BLS builds category-level price indices. Note that our index is not exactly a geometric Laspeyres Index because the weights are not week 1 weights but instead the average quantities sold in year y .

sale posted price), wholesale prices paid, and gross profits. The definition of weeks in these data also differs from Nielsen, and is aligned with the timing of the retailer’s weekly price changes. The data cover 250 stores belonging to twelve chains (`retailer_codes`) beginning in 2004 and ending in mid-2007. We focus on the largest retailer, which has 134 stores. We match 132 of these 134 stores to stores in our main sample (see Appendix Section A.1.7).

3 Descriptive evidence

3.1 Example

We begin with a visualization of pricing by a single chain (chain 128), which we choose to be representative of the typical patterns observed in our data. Figure 1a shows prices of the orange juice product. The 108 rows in the figure correspond to the 108 stores in the chain, and are sorted by income. The columns correspond to weeks from January 2006 to December 2014. The color of each store-week indicates the standardized log price p_{sjt} . Darker colors correspond to higher prices, and white indicates missing values due to zero sales.

The figure shows substantial variation of prices across weeks, with frequent sales of up to 30 log points, but virtually no variation across stores within a week. To the extent that prices vary across stores, this variation is uncorrelated with store income—i.e., the vertical position of stores in the chart. This is despite the fact that store income ranges from about \$13,000 at the bottom of the chart to about \$50,000 at the top. Figure 1b shows a similar pattern for five other products: cat food, cookies, soda, chocolate, and yogurt. Here we display just 50 of the 108 stores shown in Figure 1a, with the same 50 stores shown for the 5 products, and still ordered by income. We see variation across products in the depth and frequency of sales, but again no systematic variation of prices across stores. The pricing patterns of this chain are representative of the large majority of chains in our sample. Two additional examples are in Online Appendix Figures 1a and 1b.

While patterns like these are typical of the majority of chains, a few other chains follow a different pattern, which we will call zone pricing. Figure 2a displays an example for chain 130 (showing a random sample of 250 stores), returning to the orange juice product. Figure 2a follows the same design as Figure 1a, except that we group stores geographically by sorting them by 3-digit zip codes within states. This chain operates in 12 different states. Prices are essentially uniform within horizontal bands, but then differ for different bands. For example, stores in Georgia and Kentucky share the same pricing patterns, which are different in Illinois and most of Indiana. Note that the pricing zones are strongly correlated with state borders but do not follow them perfectly. Online Appendix Figures 2a and 2b show other examples of zone pricing.

3.2 Measures of Pricing Similarity

To describe chain pricing patterns more systematically, we introduce three measures of the extent of uniform pricing. Each measure defines the similarity of prices of a pair of stores s and s' . To compute a chain-level measure of uniformity, we average the raw measure across pairs within a chain.

The first measure is the *quarterly absolute log price difference*. We denote the average of p_{sjt} across weeks in quarter v by \bar{p}_{sjv} . We compute for each pair of stores s and s' the absolute difference in the average quarterly log price, and average this difference across the quarters and products: $a_{s,s'} = \frac{1}{N_{vj}} \sum_{v,j} |\bar{p}_{sjv} - \bar{p}_{s'jv}|$, where N_{vj} denotes the number of valid product-quarter observations.

The second measure is the *weekly correlation in prices*. We first demean the log price p_{sjt} at the store-year-product level to obtain \tilde{p}_{sjt} . Then we compute the correlation of \tilde{p}_{sjt} and $\tilde{p}_{s'jt}$, including all weeks t and over all products j which are non-missing in both store s and store s' .

These two measures capture, by design, two orthogonal aspects of similarity: differences in average prices, and correlation of price changes over time. Two stores with the same timing and depth of sales, but different regular prices would have high weekly correlation but also a high quarterly difference. Conversely, two stores with similar average prices at the quarterly level, but different timing of sales would have a low quarterly difference, but also low weekly correlation.

The third measure is the *share of (nearly) identical prices*. This is defined as price differences smaller than 1 percent, i.e. the share of observations across products j and weeks t for which $|P_{sjt} - P_{s'jt}| / ((P_{sjt} + P_{s'jt})/2) < .01$.

Figure 3 displays the distribution of these measures for store pairs in the same chain (solid blue bars) and pairs that belong to different chains (hollow red bars). To form the within-chain pairs, we keep all stores for chains with fewer than 200 stores, and a random sample of 200 stores from larger chains, and then compute similarity for all pairs within the resulting set of stores. Prices for same-chain pairs are far more similar on all three measures than for different-chain pairs. The absolute log price difference (Figure 3a) is typically below 5 log points for the former, and typically above 10 log points for the latter. The weekly correlation (Figure 3b) is typically above 0.8 for the former and below 0.2 for the latter. The share of identical prices (Figure 3c) is often as high as 0.5 or 0.6 within chain, but is rarely above 0.2 between chains.

Table 3 summarizes a number of variants of these measures. The first row summarizes the same information shown in Figure 3, reporting the mean and standard deviation of the three similarity measures for our full set of same-chain and different-chain store pairs. The second row shows that the patterns are essentially unchanged if we restrict attention to cases where stores s and s' are in the same geographic market (Designated Market Area, or DMA). The third row shows the same for cases where s and s' are in different DMAs and also face very different income levels (with one store in the pair in the top third of the income distribution and the other in the bottom third).²¹ These results

²¹Online Appendix Figure 3 displays the distribution of distance between pairs for these samples.

provide initial evidence against the possibility that the observed uniformity just reflects same-chain store pairs serving more homogeneous consumers in terms of either geography or demographics. They also suggest that it does not result from constraints specific to pairs of stores operating in the same geographic market, for example because price advertising is determined at the newspaper or television market level. The remaining rows of Table 3 show that these pricing patterns are not an artifact of focusing on our set of widely-available products. Focusing on food stores, the table shows similar patterns for: (i) the 20th-highest-selling product within a category; (ii) the top-selling store-brand product, and (iii) products with high unit-prices.²²

Figure 4 summarizes pricing uniformity at the chain level. In Figure 4a, weekly correlation is on the vertical axis, absolute log price difference is on the horizontal axis, and each point indicates the average value for a single chain. The vast majority of chains cluster in the upper-left of the figure, with low price differences and high correlation. Out of 73 chains, 61 have both an average correlation of weekly prices above 70 percent and an absolute quarterly distance in prices below 5 percent. The two measures of pricing similarity are also highly correlated: chains that are similar in one dimension are also similar in the other dimension. Deviations from this one might have expected to see *ex ante*—for example having highly correlated sales but varying the level of regular prices across stores—do not appear to a substantial degree in the data.

Figure 4b returns to the phenomenon of zone pricing. We decompose the measures of pricing similarity into similarity for pairs of stores within a state, versus across state boundaries. Focusing on chains that operate at least three stores in each of two or more states, we plot the within-state log price difference on the x axis, and the between-state log price difference on the y axis. To the extent that zone pricing follows state boundaries, it should show up in this figure as low differences within and larger differences between, i.e., points above the 45-degree line in the figure. Between differences are indeed larger in almost all cases, but for the majority of chains only slightly so; these chains do not appear to determine prices by state to a significant extent. A minority of chains do have clearer zone pricing patterns, however. Most notable is chain 9, which has an average within-state difference of roughly 2 log points but an average between-state difference of more than 9 log points.²³

3.3 Price Response to Consumer Income

We now turn to the relationship of prices to income. Stores in high-income areas have less elastic consumers (as we confirm below), so all else equal we expect these stores to charge higher prices. Though we argue that variation in marginal costs across stores is likely to be small, any such variation would likely be positively correlated with income, and so tend to strengthen this relationship.

²²In Online Appendix Figure 5, we show that chains with uniform prices for our benchmark products also tend to have uniform prices for these alternative products.

²³Online Appendix Figure 4 shows a parallel figure using correlation in weekly prices, instead of the log price difference. The classification of chains as zone pricers based on this alternative figure is overall similar.

Figure 5 shows the relationship of log income to price within and between chains.²⁴ We first regress both store average log price \bar{p}_s and store income Y_s on chain fixed effects. Figure 5a shows a binned scatterplot of the residuals, illustrating the within-chain relationship. The relationship is positive and highly significant, but the magnitude is very small economically: an increase in per-capita income of \$10,000, equivalent to a move from the 30th to the 75th percentile, is associated with an increase in prices of only 0.72 percent. Figure 5b shows a scatterplot of the chain averages, illustrating the between-chain relationship.²⁵ This is also highly significant, and its magnitude is more than five times larger: a \$10,000 increase is associated with a price increase of 4.5 percent.

We view this sharp contrast between the within and between chain results as one of our key findings. It suggests that chains are either varying their prices far too little across stores in response to income, or varying their prices at the overall chain level far too much. Our model below separates these two hypotheses, providing strong support for the former.

If we estimate the within-chain coefficients separately by chain (Online Appendix Figures 6a-c), the majority of chains have small, positive coefficients in the range between 0 and 0.01, with 27 coefficients positive and significantly different from zero. Only five chains have coefficients above 0.01. The pattern of tiny within-chain response and large between-chain response is robust to dropping the two outlier chains 98 and 124 (Online Appendix Table 2). It also holds for lower-selling and high price products, as well as for all but one module separately (Online Appendix Figure 7a).

Figures 5c-d examine the role of zone pricing. As we documented in Figures 2 and 4b, some chains vary prices more between states than within them. In Figure 5c, we re-estimate the within-chain relationship, but now plot residuals after taking out chain-state fixed effects. This further reduces the price-income slope to 0.56 percent per \$10,000 of income, but it remains statistically significant. In Figure 5d, we show the complementary plot of chain-state mean prices after subtracting the chain mean. Across states within a chain, a \$10,000 income increase is associated with an increase in prices of 2.16 percent, a slope about half the size of the between-chain relationship.

Figures 6a-d zoom into this zone pricing result for different groups of chains. For the 54 food chains that are not identified as doing zone pricing based on Figure 4b there is no relationship between chain-state income and chain-state prices (Figure 6a). There is instead a clear relationship for the 10 food chains identified as zone pricing (Figure 6b) and for the two major drug store chains (Figure 6c). The mass merchandise chains (Figure 6d) exhibit modest evidence of zone pricing.

Finally, Table 4 presents an alternative view of the price-income relationship. We run a store-level regression of average log price \bar{p}_s on both store income Y_s and the average income of stores in the chain to which s belongs. In some specifications, we include separately the average income in s 's chain-state. We separate food stores (Panel A) from the drug and mass merchandise stores (Panels

²⁴The results are similar replacing income with the fraction of college graduates (Online Appendix Figure 9).

²⁵Here we omit drug and mass merchandise chains, since comparing across formats may be less informative and the number of chains for these channels is small. Online Appendix Figure 8 shows the plot including these chains. The overall pattern remains unchanged.

B and C), since it is only for the food stores that we can do a meaningful between-chain comparison. The first column presents the regression including only own-store income as a benchmark.²⁶ The second column adds chain average income for food stores. Consistent with the evidence in Figure 5, a store’s response to its own consumers’ income is an order of magnitude smaller than its response to the average income served by its chain. This result remains when we add county fixed effects (third column). Thus, if we look at two stores in the same county both attracting consumers of the same income, one of which is from a mainly high-income chain and one of which is from a mainly low-income chain, the former will tend to charge much higher prices than the latter. The fourth and fifth columns add chain-state average income as a regressor. This response is larger than the own-store-income response but smaller (for food stores) than the response to overall chain average income, consistent with our other zone pricing results.

3.4 Composition Bias

The pattern of within-chain pricing in Figure 5a-c poses a puzzle. Why would chains exert the effort to vary their prices in a highly systematic way with consumer income, but then do so with an economically tiny magnitude far smaller than the one with which they respond to income at the chain level, and far smaller than the analysis below suggests would be profit maximizing? We show here that this small price-income relationship is likely to be mainly an artifact of composition bias, due to the fact that the standard Nielsen price measure is the weekly average price paid rather than the price the store posted at any given point in time.

If all consumers of a store in a given week paid the same prices, weekly average price paid and posted price would be equal. For them to diverge, prices paid must vary within a week. There are two main reasons why they are likely to do so. First, Nielsen’s weekly revenue and units sold are based on a week that runs from Sunday through Saturday. Although most retailers do not change prices at more than weekly frequency, they may institute their price changes on a different day of the week. If, for example, they change prices on Wednesdays, consumers who buy in the first half of Nielsen’s week will pay a different price from those who buy in the second half. Second, some but not all consumers may use store cards or obtain other discounts that lead them to pay lower prices.

For an example of the bias that can arise, consider a retailer that charges identical prices in all stores and that changes prices on Wednesdays. Suppose in a particular week they cut the price from P^{high} to P^{low} . The measured weekly average price in the Nielsen data for store s will be $P_s^{RMS} = \theta_s P^{high} + (1 - \theta_s) P^{low}$, where θ_s is the share of purchases made in the first half of the week in store s . If the share θ_s varies across stores for any reason, this will obscure the fact that the chain is charging uniform prices. In fact, the share θ_s will vary systematically: for stores facing

²⁶For mass merchandise stores, there is a negative relationship between prices and income when not including chain fixed effects because among the largest two mass merchandise chains, the one operating in, on average, higher income areas has lower prices (see Online Appendix Figure 8b).

less elastic consumers, fewer will shift purchases to the low price, and θ_s will be higher. Measured prices P_s^{RMS} will thus be higher for stores facing higher income or otherwise less elastic consumers, even if posted prices do not vary at all. A similar bias arises if the share of consumers who use store cards or other discounts is greater among consumers who are most price elastic.

This bias can explain a price-income gradient broadly consistent with what we observe. Suppose that the income of store s is \$10,000 greater than the income of store s' , and that, consistent with our estimates of the income-elasticity relationship below, this translates into price elasticities among their respective consumers of $\eta_s = -2.5$ and $\eta_{s'} = -2.65$. Suppose that P^{low} is 35 percent lower than P^{high} , and that the price change occurred exactly midway through the Nielsen week. Consistent with our model below, assume a constant-elasticity demand function $Q_s = kP_s^{\eta_s}$. Then it is straightforward to show that $(\theta_s, \theta_{s'}) = (0.328, 0.318)$, and the difference in log prices is $p_s^{RMS} - p_{s'}^{RMS} = 0.006$.²⁷ If prices go on sale and off of sale every four weeks, this would imply a bias in one fourth of the weeks, and thus a slope of 0.0015 in the analogue of Figure 5c. This mechanical bias thus could explain a quarter of the observed slope across all stores (0.0056 in Figure 5c) and half of the slope for food stores (0.0029, Online Appendix Table 2). Taking into account also the bias from heterogeneity in the share of consumers with store cards, the composition bias could plausibly account for all the observed variation of prices within the majority of chains.

To provide direct evidence on the magnitude of this bias, we use the major grocer data described in Section 2. This grocer does, indeed, change prices every week on Wednesday, and the revenue and units sold reported in the grocer’s data are based on weeks defined Wednesday-Tuesday. We therefore expect the bias arising from mid-week price changes to be present in the Nielsen data but not in the grocer’s data. Figure 7a shows a bin scatter of the within-chain relationship using the Nielsen price measure for the 132 stores in both data sets. This grocer uses geographic pricing zones, so we focus on the within-chain-state relationship as in Figure 5c. The slope of 0.0027 is similar to the one in Figure 5c and marginally significant. Figure 7b reproduces the same estimate, but using weekly prices from the grocer’s data. The estimated slope falls to 0.0008 and is no longer significantly different from zero. We thus cannot reject the view that posted prices for this retailer do not vary at all with income, and that all of the within-chain-state slope for this retailer is an artifact of the weekly offset. Figure 7c shows the same slope using the posted non-sale price, which we observe in the grocer data. This is not the object we would ideally like to measure—if stores vary the frequency or depth of their sales we would consider this real variation in posted prices—but it provides a benchmark. Here all remaining slope disappears: this chain sets uniform non-sale prices with respect to income. We observe further that, within a state, 74 percent of store pairs charge identical non-sale prices (i.e., within 1 percent as defined above).

²⁷To see this, note that $\theta_s = \frac{q_s^{high}}{q_s^{high} + q_s^{low}} = \frac{(P^{high})^{\eta_s}}{(P^{high})^{\eta_s} + (P^{low})^{\eta_s}}$. Plugging in the values for P^{high} , P^{low} , η_s , and $\eta_{s'}$ yield the values of $(\theta_s, \theta_{s'})$ which in turn yield values of P_s^{RMS} and $P_{s'}^{RMS}$.

As an additional check about the importance of this bias, we use an algorithm described in Appendix Section A.1.8 to estimate non-sale prices in the Nielsen data and repeat the analysis of Figure 5. Online Appendix Figures 10a-d show that this flattens the within-chain price-income relationship but not the between-chain relationship.

Our conclusion is that a large part of the within-chain and within-chain-state slopes shown in Figure 5 are likely an artifact of composition bias. We suspect that a large majority of chains are in fact charging exactly the same prices in all of their stores, or in all stores within geographic zones. Moreover, we note that this bias will not only affect the cross-sectional relationship of prices and income, but also the apparent response of prices to income shocks observed in panel data. We discuss the implications of this bias for the literature on local price responses in Section 6 below.

3.5 Variation in Marginal Cost

Stroebel and Vavra (2015) provide a detailed analysis suggesting that variation in marginal costs among retailers such as those in our data is likely to be negligible. They first use novel data on wholesale costs to show that geographic variation in these costs is minimal. Since wholesale costs account for three-quarters of total costs, and a presumably much larger share of marginal costs, this significantly limits the scope for cost variation. They then go on to present further evidence suggesting that neither variation in labor costs nor variation in retail rents plays a significant role.

We confirm the findings for wholesale costs in our large grocer’s data. A bin scatter of the wholesale cost variable for this grocer against store income (Figure 7d) displays no evidence of a positive relationship between the two variables. Given this evidence, we will assume for the remainder of our analysis that marginal costs are constant across stores within a chain.

4 Demand estimation and optimal prices

4.1 Model

We introduce a simple demand model to gauge the degree to which we would expect prices to vary within and between chains. The model makes strong assumptions, and we do not necessarily take deviations from the model predictions to imply a failure of profit maximization. It provides a valuable benchmark, however, on the extent to which short-run pricing incentives vary across stores.

A monopolistically competitive chain chooses a price P_{sj} for each product in each of its stores to maximize total profits. Each store’s residual demand for product j takes the constant elasticity form $Q_{sj} = k_{sjw}P_{sj}^{\eta_s}$, where Q_{sj} is the number of units sold, k_{sjw} is a scale term that may vary seasonally by week of year w , and η_s is the store’s price elasticity. Total cost $c_jQ_{sj} + C_s$ for a store

consists of a constant marginal cost c_j and a store-level fixed cost C_s . The chain solves

$$\max_{\{P_{s,j}\}} \sum_{s(c),j} (P_{sj} - c_j) Q_{sj}(P_{sj}) - \sum_{s(c)} C_s. \quad (1)$$

The first order conditions yields, for all j ,

$$P_{sj}^* = \frac{\eta_s}{1 + \eta_s} c_j \quad (2)$$

or in log terms

$$p_{sj}^* = \log\left(\frac{\eta_s}{1 + \eta_s}\right) + \log(c_j). \quad (3)$$

There is thus a simple relationship between elasticities and optimal prices, and under optimal pricing a regression of log prices on $\log\left(\frac{\eta_s}{1 + \eta_s}\right)$ within chains should yield a coefficient of one.

4.2 Elasticity estimates

The model above requires estimates of the store-level elasticity of demand η_s . As our benchmark measure, we estimate the response of weekly log quantity to the weekly log price product-by-product, for each store s . More precisely, letting $q_{sjt} = \log(Q_{sjt})$, we estimate separately for each store s ,

$$q_{sjt} = \eta_s p_{sjt} + \alpha_{sjy} + \gamma_{sjw} + \epsilon_{sjt}, \quad (4)$$

where α_{sjy} is a product-year fixed effect, γ_{sjw} is a product-week-of-year fixed effect, and ϵ_{sjt} is an error term. The former controls for the fact that the exact UPC associated with a product varies in some cases across years, and the latter captures seasonal variation in k_{sjw} . The coefficient on the log price is the estimated price elasticity, $\hat{\eta}_s$. We use price variation for all 9 years and all 10 products in order to maximize precision. We cluster the standard errors by bi-monthly periods, thus allowing for correlation across products, as well as over time within a 2-month period.

This stylized demand structure abstracts away from two important margins: inter-temporal substitution and cross-product substitution. The former could lead quantities in week t to vary with prices in prior weeks. The latter could lead to demand for one product to depend on the price of other products. We revisit these assumptions below.

To adjust for sampling error in the elasticity estimates, we use a simple empirical shrinkage procedure. We re-estimate the elasticity using just the first 26 weeks of each year and again using the next 26 weeks of each year; label these elasticity estimates $\hat{\eta}_{1,s}$ and $\hat{\eta}_{2,s}$. We choose a shrinkage parameter ρ to minimize the mean squared difference between $(1 - \rho)\hat{\eta}_{1,s} + \rho\bar{\eta}_1$ and $\hat{\eta}_{2,s}$, where $\bar{\eta}_1$ is the overall mean of $\hat{\eta}_{1,s}$ across stores.²⁸ The estimated optimal shrinkage is just $\hat{\rho} = .104$ for food

²⁸Online Appendix Figure 11 shows the mean squared error as function of the shrinkage parameter.

stores, though it is slightly larger at $\hat{\rho} = .305$ for drugstores and $\hat{\rho} = .408$ for mass-merchandise stores. We then adjust our overall estimates $\hat{\eta}_s$ as $\tilde{\eta}_s = (1 - \hat{\rho}) \hat{\eta}_s + \hat{\rho} \bar{\eta}$, where $\bar{\eta}$ is the mean of $\hat{\eta}_s$.

Figure 8a shows the distribution of the resulting elasticity estimates $\tilde{\eta}_s$ for food, drug, and mass merchandise stores. All are well-behaved, with all but a handful of values less than the theoretical maximum of -1 , and most of the mass falling between -2 and -4 . Figure 8b shows the distribution of associated standard errors, which are mostly between 0.05 and 0.2 for food stores and between 0.2 and 0.4 for drugstores and mass-merchandise stores. The lower precision for the latter is expected given the smaller number of products in the drug and mass-merchandise samples.

Figure 8c provides evidence on the fit of the constant elasticity demand model. The figure shows a binned scatter plot of residuals of q_{sjt} against residuals of p_{sjt} after partialing out the fixed effects α_{sjy} and γ_{sjw} . The model predicts a linear relationship, and the results suggest that it is to a remarkable degree. This plot aggregates across all products and tens of thousands of stores of all types. Visual inspection of this relationship by product and store-by-store generally yields similarly well-behaved linear relationships (with different slopes, as expected given the different mean elasticity estimates for each store type and module); some examples are in Online Appendix Figures 12a-b.

We provide two additional pieces of evidence validating the elasticity estimates for food stores in Online Appendix Figures 12c-d. First, the log price variable explains about half of the remaining variation (in terms of R^2) after controlling for the fixed effects. Second, we run a module-by-module regression that pools across stores and augments equation (4) by including also the prices charged in weeks $t - 2$ and $t - 4$, as well as in week $t + 4$ (and using a store-year fixed effect μ_{sy} in place of the product-year fixed effect α_{sjy}). The coefficients on these variables, while statistically significant and in line with the predictions of a model of stockpiling, are an order of magnitude or more smaller than the coefficients on price in week t . Furthermore, they are not systematically larger for storable products, like toilet paper and canned soup, than for non-storables, like orange juice and yogurt.

Finally, we examine the correlates of our estimated elasticities. Figure 8d shows that the estimated elasticities vary monotonically (and in fact linearly) with store income. Table 5 presents regressions of the estimated elasticities $\tilde{\eta}_s$ on a broader set of demographic and competition measures. The results confirm the robust relationship between elasticity and income: an increase of \$10,000 is associated with an increase of the elasticity of 0.140 (s.e. 0.014). This estimate remains similar with the addition of chain fixed effects. In columns 3 and 4, we add as determinants the share of college graduates, the median home price, controls for the percent urban share, as well as a simple measure of competition with other stores: indicators for the number of other food stores within 5 kilometers of the store. The coefficients generally have the expected sign, with income as the strongest determinant, and a weak, but correct-signed, effect of the competition proxies.²⁹

Next, we replace the estimated elasticity $\tilde{\eta}_s$ as the dependent variable with the log elasticity

²⁹Column 5 in Online Appendix Table 4 shows that it is important to control for the percent urban variables, as without those the competition variables have the opposite sign (though their effect is not significant).

term $\log\left(\frac{\tilde{\eta}_s}{1+\tilde{\eta}_s}\right)$ suggested by equation (3). The regressions in columns 6-8 are the first-stage of the instrumental variables regressions we estimate below. Income is a strong predictor of log elasticity, with a coefficient that is relatively similar across food, drug, and mass-merchandise stores.

4.3 Comparing observed and optimal prices

In this section, we bring to the data the specification of equation (3), which optimal pricing as a function of the store-level elasticity. In particular, we estimate

$$\bar{p}_s = \alpha + \beta \log\left(\frac{\tilde{\eta}_s}{1+\tilde{\eta}_s}\right) + \epsilon_s. \quad (5)$$

Specification (5) follows from averaging equation (3) across products. Under the assumptions of the model the coefficient β on the log elasticity term is equal to 1. If the chains under-respond to the elasticity variation, instead, we will observe $\beta < 1$. For our benchmark specification, we instrument the log elasticity term with the store-level income to address remaining measurement error in these estimates.³⁰ The standard errors are block bootstrapped, clustering by `parent_code` in food stores to allow for any within-chain correlation in errors. For the drugstores and mass-merchandise stores, given that there are only, respectively, 4 and 5 chains, we block bootstrap by `parent_code*state`.³¹ Figure 9 displays the first stage relationship between the log elasticity term and income within chain, between chains, and within and between chain-states. Unlike the analogous plots of the price-income relationship in Figure 5, the within and between relationships are remarkably similar, with a first stage coefficient varying between 0.034 and 0.055.

We estimate variants of this IV regression within and between chains and chain states. To compute within-chain estimates we replace α with chain fixed effects. To compute within-chain-state estimates we replace α with chain-state fixed effects. To compute between-chain-state estimates we average \bar{p}_s and the log elasticity term within chain states, and run the regression including chain fixed effects. To compute between-chain estimates we average both terms within chains and then run the regression with no fixed effects. In all cases, we fix the first-stage coefficients at the values from the within-chain first stage shown in the final three columns of Table 5. This is motivated by the similarity of the coefficients in Figure 9, and prevents us from losing first-stage power in the specifications where we aggregate the data.

Table 6 presents our main IV estimates, starting with the food stores. The first two columns show within-chain and within-chain-state results respectively. Both coefficients are statistically significant, but an order of magnitude smaller than the model prediction of $\hat{\beta} = 1$. Thus, the

³⁰For this specification we winsorize the store elasticity $\tilde{\eta}_s$ at -1.2. This happens very rarely in the case of our benchmark weekly elasticity estimates (nine food stores and one drugstore) but more frequently for weekly index (564 food stores) and quarterly top-product estimates (796 food stores).

³¹We cluster by `parent_code` instead of by chain (`retailer_code`) to allow for correlation between chains that fall under the same ultimate owner (`parent_code`).

observed near-uniform pricing within chain occurs despite significant incentives to vary prices to achieve profit maximization. The third column shows between-chain-state estimates. The results imply a substantial response of income to the elasticity term, though smaller than predicted by the model, $\hat{\beta} = 0.351$ (*s.e.* 0.193). Finally, the fourth column shows the between-chain estimates. The estimated coefficient on the log elasticity term in this regression, $\hat{\beta} = 0.944$ (*s.e.* 0.220), indicates that average pricing at the chain level is consistent with the model: we cannot reject a slope $\beta = 1$.

In the drug stores (Panel B) the within-chain response is larger, but still significantly smaller than predicted by the model: $\hat{\beta} = 0.287$ (*s.e.* 0.040). The between-chain-state relationship (zone pricing) is consistent with the model: $\hat{\beta} = 0.858$ (*s.e.* 0.267). In the mass merchandise stores (Panel C) the response is intermediate between the one for food stores and that for drug stores.

We present OLS estimates parallel to Table 6 in Online Appendix Table 5 and Online Appendix Figures 13a-d. We find qualitatively similar results, but the point estimates are about 3 times or more smaller. This may reflect measurement error in our estimated elasticities. It may also reflect a larger local average treatment effect in the IV regressions due to variation in income being more salient to chains than variation in other determinants of elasticities. The OLS results reinforce the conclusion that the within-chain price-elasticity relationship is more than an order of magnitude too flat to be consistent with the model.

4.4 Robustness

Table 7 presents a series of robustness checks, focusing on the results for food stores.

Quarterly Elasticities. Our short-run elasticities may differ from the longer-run elasticities that are relevant to the chains' pricing problem. Longer-run elasticities could be smaller due to stock-piling, or larger if it takes consumers time to adjust to price changes—for example, if price increases induce gradual substitution to other stores. As a step toward addressing these concerns, we estimate quarterly elasticities. That is, we average the weekly log price and log units sold across all weeks in a quarter, and then re-estimate our main equation (4). The controls include the year-product fixed effects as well as quarter-of-year*product fixed effects. The estimated quarterly elasticities are smaller (in absolute value) than the benchmark ones (Online Appendix Figure 15a) but the two measures are highly correlated (Online Appendix Figure 15b). Importantly, the quarterly elasticity measure passes the same validation exercises as our benchmark measure, as Online Appendix Figures 15c-e document: (i) the log-log specification is approximately linear; (ii) the standard errors of the estimated elasticity are still relatively small (at .15 to .4), even if clearly larger than in the benchmark elasticities,³² and (iii) the measure is still highly correlated with local income.

Panel A of Table 7 reports our main IV results using the quarterly elasticity measure, with the first stage reported in Online Appendix Table 4. The finding that within-chain responses are an

³²We cluster the standard errors for the quarterly elasticities at the quarterly level, allowing for correlation across the 10 products.

order of magnitude too small is robust to using the quarterly measure. In fact, the within-chain $\hat{\beta}$ coefficients become substantially smaller. This reflects two offsetting forces: the quarterly elasticities vary less across stores, which would tend to reduce the optimal price variation, but the fact that they are lower in magnitude makes the log elasticity term $\log\left(\frac{\eta_s}{1+\eta_s}\right)$ more responsive to a given change in elasticity. The smaller coefficient, and the consequently larger gap between actual and predicted price variation, means that the second effect dominates. The between-chain relationship is still an order of magnitude larger than the within-chain response, but is now significantly smaller than the model predicts ($\hat{\beta} = 0.340$).

Module-Level Indices. Another important limitation of our model is the fact that it ignores substitution between products. Firms care about the profits they earn from all products. If some of the response in our benchmark elasticities reflects within-store substitution, the optimal price response could be smaller than our model would predict. To partially address this issue, we re-estimate our elasticities using the module-level price and quantity indices described in Section 2. As in the case of the quarterly elasticities, the module-level price elasticities are smaller (in absolute value) than the benchmark ones (Online Appendix Figure 16a), as expected, but are highly correlated with the benchmark elasticity (Online Appendix Figure 16b). The index elasticity also passes the same validation tests (Online Appendix Figures 16c-e).

In Panel B of Table 7 we regress the price index on the index elasticities, instrumented with income.³³ As with the quarterly elasticities, this yields even smaller within-chain coefficients: our main finding that chains vary prices too little from the model’s perspective is robust. Here we cannot re-estimate the between-chain specifications given that the price indices are not comparable across chains. In Online Appendix Table 6, Panel A we show that the within-chain results are similar if we use the index elasticity while keeping the benchmark prices as the dependent variable.

Additional Robustness. So far we have used per-capita income as an instrument for the log elasticity term. The results are very similar (Panel C) if instead we use the full set of demographic and competition variables in columns (3) and (4) of Table 5. In Panel D, we consider the role of branding by considering the price of a top-selling generic that is common to many chains within a subset of the modules considered. The within-chain relationship of pricing to income or elasticity remains very similar to the one for the top-selling branded good. In Online Appendix Table 6, we show that these patterns persist when using the 20th most-available good in each of the 10 product categories as dependent variable (Panel B), generic top sellers within chains (Panel C) and some high-quality (high-price) products (Panel D).³⁴

Yearly Average Price Paid. Our main question of interest is how the pricing decisions of firms compare to the benchmark of optimal pricing, and we are therefore interested mainly in the prices firms choose to post. If we are interested in the welfare effects on consumers, however, we

³³The first stage is in Online Appendix Table 4.

³⁴Online Appendix Figure 14 presents the within-chain and between-chain plots for these alternative products.

may also want to consider the average price paid over a longer time horizon. When prices vary over time, more elastic consumers could end up paying substantially lower prices on average than less elastic consumers even if the posted prices they face are the same.

To assess how large this force is, in Table 8 we compare our benchmark results with the log of the weekly average prices (Panel A) with the results for the log of the yearly average prices (Panel B). The within-chain coefficient ($\hat{\beta} = 0.223$) for the yearly average prices, while larger than the benchmark estimate in Panel A as expected, is still 5 times smaller than the model prediction under optimal pricing ($\beta = 1$). Thus, even taking into account this margin of adjustment does not bring the level of prices up to what is expected in light of the model. Still, it is interesting that the presence of sales works as a kind of “automatic” price discrimination, guaranteeing that consumers in more-elastic stores pay lower prices over the year, even in presence of uniform pricing.³⁵

4.5 Loss of Profits

The model allows us to compute the profits lost as a result of near-uniform pricing. Under uniform pricing, we assume that a chain c sets a constant price \bar{P}_{jc} across all stores s to maximize

$$\max_{\{\bar{P}_{cj}\}} \sum_{s(c),j} [\bar{P}_{cj} k_{sj} \bar{P}_{cj}^{\eta_s} - c_{cj} k_{sj} \bar{P}_{cj}^{\eta_s}] - \sum_{s(c)} C_s,$$

where $s(c)$ is the set of stores s belonging to chain c . This leads to the first order condition

$$\sum_{s(c)} k_{sj} [(1 + \eta_s) \bar{P}_{cj}^{\eta_s} - c_{cj} \eta_s \bar{P}_{cj}^{\eta_s - 1}] = 0. \quad (6)$$

We assume that each chain c sets their average price \bar{P}_{cj} equal to the solution to (6). This is a much weaker assumption than the standard assumption of profit maximization, and is consistent with the between-chain results observed above. To compute the implied profits, we need estimates for the scale factor k_{sj} , the marginal costs c_{cj} , and the fixed cost C_s , in addition to the elasticities η_s which we already estimated.³⁶ To estimate the quantity term, we use $\hat{k}_{sj} = Q_{sj} / P_{sj}^{\tilde{\eta}_s}$, where Q_{sj} is the average over all weeks t of the quantity sold Q_{sjt} . To estimate the marginal costs, we define $\hat{c}_{cj} = \left[\sum_s \hat{k}_{sj} (1 + \tilde{\eta}_s) \bar{P}_{cj}^{\tilde{\eta}_s} \right] / \left[\sum_s \hat{k}_{sj} \tilde{\eta}_s \bar{P}_{cj}^{\tilde{\eta}_s - 1} \right]$, which by equation (6) is a consistent estimator. Finally, to estimate the fixed costs, we follow Montgomery (1997), who estimates gross profit margins for supermarkets of 25 percent and operating profit margins of 3 percent; thus we posit $\hat{C}_s = 0.88 * \Pi_s^g$, where Π_s^g is the (optimal) gross profit.

³⁵Online Appendix Figures 17a-d reproduce the key findings in Figure 5a-d, comparing the yearly average price to the weekly average price. The yearly average price is more responsive to within-chain differences in income than the weekly average price (Online Appendix Figures 17a and 17c), with a slope that is about twice as steep. Similarly, the between-state zone-pricing relationship is also stronger using the yearly average price (Online Appendix Figure 17d). The between-chain relationship for food stores, instead, is not much affected (Online Appendix Figure 17b).

³⁶For the computation of the lost profits, we use the modules with constant products throughout the 9 years so as to avoid estimating year-specific marginal cost and quantity terms.

Given these assumptions, we compute the profits for store s and product j under uniform pricing, $\bar{\Pi}_{sj}$, and under optimal pricing, Π_{sj}^* , which we obtain setting $P_{sj}^* = \hat{c}_{cj} * \tilde{\eta}_s / (1 + \tilde{\eta}_s)$.³⁷ We then aggregate across products j to obtain $\bar{\Pi}_s$ and Π_s^* , and compute the percent of profit loss due to uniform pricing as $(\Pi_s^* - \bar{\Pi}_s) / \Pi_s^*$. Panel A of Table 9 shows that in the average store the profit loss is 8.9 percent of variable profits, with the losses as high as 23 percent at the 90th-percentile store. The highest losses occur for stores in high-income areas (Online Appendix Figure 18a), where the lower elasticities (in absolute value) would call for significantly higher prices under flexible pricing.

While uniform pricing captures well the observed pricing in most food chains, we did estimate a small, but statistically significant, response of prices to elasticity within chains. In the second row of Table 9 we compute the percent profit loss for the actual profits Π_s , relative to optimal pricing. To compute the actual profits, we use the prices implied by our benchmark IV specification: $P_{sj} = A_{cj} * [\tilde{\eta}_s / (1 + \tilde{\eta}_s)]^{\beta_{IV}}$, where β_{IV} is the estimate in Column 1 of Table 6 and A_{cj} is a constant that guarantees that the average price P_{sj} across all stores s in chain equals the uniform price \bar{P}_{cj} .³⁸ We then compute the profits Π_{js} and aggregate across products j . The second row in Panel A of Table 9 shows that this tempers the losses to an average profit loss of 6.5 percent. In the final row, we compare this loss to the loss of profits for state-zone optimal pricing, where prices are set optimally, but are uniform at the state level. The losses from this state-zone optimal pricing are similar to the estimated profit using the actual price-elasticity slope.

In Panel B of Table 9 we aggregate the profits for all stores $s(c)$ in a chain c , and compute the chain-level profit loss $(\Pi_c^* - \bar{\Pi}_c) / \Pi_c^*$. The mean loss from uniform pricing at the chain level is 8.7 percent, and the mean loss using the actual price-elasticity slope is 6.9 percent. For the average food chain (Online Appendix Table 7), the profit loss from uniform pricing is about 8.8 percent, and 7.2 percent under the actual pricing. For the drug store chains, the loss from uniform pricing is larger, even when taking into account the more sizable price-elasticity slope. Finally, the losses are smaller for the mass merchandise chains.³⁹

5 Determinants of Pricing and Explanations

In this section, we discuss chain-level factors that predict uniform pricing, then turn to possible explanations.

Determinants of Flexible Pricing. Table 10 shows the relationship between the degree of uniform pricing and chain characteristics. The dependent variable is a chain’s estimated response

³⁷For the stores with elasticity $\tilde{\eta} > -1.2$, the elasticity is winsorized at -1.2.

³⁸If we instead use the observed prices, the estimated lost profits would be much larger, as there is significant idiosyncratic variation in these prices which is both unrelated to income and sub-optimal from the perspective of our model.

³⁹Online Appendix Table 7 also displays the profit loss computed using the actual prices, as opposed to using prices from the price-elasticity slope. The profit losses are computed to be higher, given that prices vary for other reasons that our model does not capture.

to the log elasticity term in equation (5), based on chain-by-chain estimate of the IV specification in Column 1 of Table 6, where we pool chains in the first stage.⁴⁰

We first relate this measure of flexible pricing to measures of chain size: the log number of stores, the log number of states the chain operates in, and the log of average revenue per store. As Column 1 of Table 10 shows, both the number of stores and the average revenue positively predict flexible pricing. Just these three variables achieve an $R^2 = 0.523$, implying that chain size is an important determinant of the uniformity decision.

Next, we add a reduced-form measure of the returns from flexible pricing: the standard deviation of store-level income across the stores in the chain. As Column 2 shows, even controlling for chain size, heterogeneity in income across stores is a significant predictor of flexible pricing.

We then consider two model-based variables of the return to tailored pricing: the percentage gains from optimal pricing, $(\Pi_c^* - \bar{\Pi}_c) / \Pi_c^*$, as in Table 9, and the log absolute gain from optimal pricing, $\log(\Pi_c^* - \bar{\Pi}_c)$. To compute this second variable, we take the store-level loss from uniform pricing in dollar terms, $\Pi_s^* - \bar{\Pi}_s$, and scale it up by the share of revenue in that store due to the selected UPCs; we then sum the dollar losses across all stores in a chain, and take the log.

The percent profit loss is likely the most relevant variable if the chain is comparing the gain to optimal pricing to a store-by-store cost of optimal pricing, such as for example the possible backlash from consumers who may perceive optimal pricing to be unfair. The profit loss in dollars is more relevant if the chain is comparing the gain to optimal pricing to a chain-wide fixed cost, such as a chain-wide managerial cost. As Column 3 shows, of the two variables, only the (log of) the dollar profit losses is significant, consistent with the results in Columns 1 and 2 which suggest that the chain size matters. While the log dollar profit loss is clearly correlated with the extent of tailored pricing (see Online Appendix Figures 18b for a scatterplot at the chain level), the explanatory power of these two variables ($R^2 = 0.3$) is about half the one for Column 2.

Next, in Column 4 we consider two variables that one would expect to play a role according to some of the possible explanations for the findings. As a measure of competition, we take the share of stores of chain c that have at least a competitor store within 10 km. Stronger competition could lead one to expect a stronger incentive to charge optimal prices. Conversely, though, as discussed below, tacit collusion incentives could lead one to expect the opposite. We also consider a measure of density, the share of stores which have a second store of the same chain within 10 km. If consumers compare prices across stores in the same chain and disliked price variation due to fairness, varying prices will be less attractive for contiguous stores. We find that neither variable matters significantly.

Finally, in Column 5 we consider all determinants together. A key size variable—the average store sales—remains a strong determinant, as does a variable the indicates the dispersion of con-

⁴⁰That is, for each chain we regress the store-level log price on the store-level income, yielding the coefficients in Online Appendix Figure 6. We then divide these coefficients by the first-stage coefficient in Table 5, Columns 6-8 (depending on chain type). For example, for grocery chain 32 the coefficient is $0.0098/0.0474 = 0.207$.

sumer demand across store—the heterogeneity of income. The two model-based measures are not statistically significant, though they are highly correlated with the other determinants. In Online Appendix Table 8 we document similar results using the quarterly absolute log price difference at the chain level, as in Figures 4a-b.

Explanations. In light of this evidence, we now consider explanations for the documented prevalence of uniform pricing. Some traditional explanations do not appear to apply to this setting. One is **menu costs** (Mankiw, 1985). Grocery stores change prices regularly to implement sales. Thus, it is implausible that a menu cost limits the ability to set different prices at the store level, especially since store-level heterogeneity in income is persistent, and thus local prices would have to be updated only rarely. A behavioral explanation that also appears unlikely in this setting is **limited attention** on the part of managers (e.g., Gabaix and Laibson 2006). It is hard to imagine that managers are not aware, or are optimally inattentive, with regards to the the local income in their stores, especially given that we consider local income averaged over several years.

We also think it is unlikely that uniform pricing is due to constraints imposed by price **advertising**. Advertising could certainly create an incentive to price uniformly within a geographic market: if a firm advertises a particular price in a newspaper, for example, it might want to honor that price in all stores in that newspaper’s circulation area. Retail chains rarely advertise prices nationally, however, and this constraint would only apply at the level of a newspaper market or at most a television market (DMA) which is typically larger. In Online Appendix Figures 19a-b we compare the zone pricing at the state level to the zone pricing at the DMA level (after taking residuals for state-chain fixed effects). We find *less* evidence of zone pricing at the DMA level than at the state level, and we see many chains that charge nearly uniform prices across DMAs.

We see three other explanations as more plausible. First, committing to uniform or zone pricing may allow chains to **soften price competition**. Intuitively, suppose chains start out in a high-price equilibrium, and that they would be tempted to cut prices in certain markets to capture market share from their competitors. Under flexible pricing they could do so while leaving their other stores’ prices unchanged. Under uniform pricing, such price cuts become more costly, as the chain would be forced to cut prices in all stores. Dobson and Waterson (2008) present a model in which committing to uniform pricing softens competition. Adams and Williams (2017) estimate a richer model in which this incentive exists and find mixed support for it as an explanation using data from the hardware industry.

A basic prediction of such models is that the value of committing to uniform pricing would tend to be greater for chains that face significant competition than for chains that do not. We do not observe any chains that are literally monopolists in all their markets, but there is substantial variation in the extent of competition chains face. As one piece of evidence in our context, we showed in Table 10 that the share of stores in a chain facing competitors nearby is not a predictor

of the extent of uniform pricing. Further, in Online Appendix Table 9 we ask whether the price-log elasticity relationship differs for stores with no competing stores nearby. There is no evidence for food and drug stores. These exercises are not a definitive test – the incentive to soften competition in this way need not be related in a simple way to our competition proxies – but we see them as evidence suggesting that softening price competition may not be the driving force.

Second, managers may avoid varying prices because they are concerned consumers could perceive charging different prices in different stores as unfair (**fairness**). If varying prices would damage the reputation of the chain as a whole, this might outweigh the gains from changing prices at specific stores. Anecdotal evidence from store managers themselves provides some support for this explanation. In a report on the UK grocery pricing, the UK Competition Commission writes “*Asda said that it would be commercial suicide for it to move away from its highly publicized national EDLP pricing strategy and a breach of its relationship of trust with its customers, and it would cause damage to its brand image, which was closely associated with a pricing policy that assured the lowest prices always*” and “*Morrisons stated that adopting a policy of local prices would be contrary to its long-standing marketing and pricing policy, it would damage its brand and reputation built up over many years and would adversely affect customer goodwill, as well as being costly to implement and manage*” (Competition Commission, 2003).

These quotes notwithstanding, several facts suggest fairness may be a less compelling explanation for uniform pricing in our setting than in others. First, few consumers visit multiple stores from a chain in geographically separated markets, so if chains did choose to price discriminate across these stores few consumers would observe this directly. Second, price variation across markets is common in other domains (e.g., gasoline, local services) and does not provoke any fairness outcry. Finally, if our chains were to price discriminate they would be raising prices on the rich and cutting them for the poor (as we discuss in Section 6.1 below), not an obviously objectionable practice from an ethical point of view.

If fairness was a key driver, we would expect to see more price uniformity when detecting price variation is easier for consumers. One proxy for this would be the share of stores in a chain that are close to other same-chain stores. As we showed in Table 10, there is no evidence that chains with a higher fraction of isolated stores are more likely to do targeted pricing. Further, in Online Appendix Table 9 we consider if stores with no same-chain other stores nearby are more likely to price to elasticity. We find no evidence for food store or mass merchandise stores, with some evidence for drug stores. Overall, we find only limited support for the fairness explanation.

A final explanation is **managerial decision-making costs**. Implementing more flexible pricing policies may impose costs such as up-front managerial effort in policy design or investments in more sophisticated information technology. More generally, the costs of implementing sophisticated pricing policies may exhibit increasing returns to scale. Bloom and Van Reenen (2007) offer possible support

for this, showing that larger chains have better management practices generally. To the extent that uniform pricing has been the prevalent policy in the past, change may impose additional costs, as managers may not be well incentivized to take the change, while fearing the cost if a change backfires.

The key prediction of any such model is that chains should invest more in flexible pricing when the returns to doing so are high. In particular, we would expect to see more such investment for large chains in terms of number of stores and revenue, and in chains where the variation of optimal prices across stores is large. The findings in Table 10 strongly support these predictions.

Another possible prediction is that pricing would become more flexible over time, as information technology costs fall and inertial managers turn over. Panel B in Online Appendix Table 9 shows the results of our benchmark IV specification, forming the log price variable either using the first years in our sample (2006-08) or the most recent years (2012-14). We find that both drug and mass merchandise chains appear to have doubled the flexibility of their pricing over these years, though we do not see a comparable trend for grocery chains.

Overall, though none of this evidence is definitive, we see the most support for managerial decision-making costs or inertia, consistent with prior work on management and behavioral firms (e.g., Bloom and Van Reenen, 2007 and Hanna, Mullainathan, and Schwartzstein, 2014).

6 Implications

In this Section, we consider three broader economic implications of uniform pricing.

6.1 Inequality

Jaravel (2016) among others brings attention to the role of store pricing for the rise of inequality in the past decades, and shows that the introduction of novel products reduced the relative prices faced by high-income consumers. Uniform pricing by chains will have a similar effect, since optimal prices covary positively with income.

To quantify this effect, we compare the relationship between average local prices and income to the counterfactual one we would observe if firms priced flexibly as in our benchmark model. We compute the observed level of prices at a particular income level by simply taking the average price charged by stores in all chains with local income in that range. For the counterfactual, we compute the optimal price under flexible pricing as detailed in Section 4.5: $p_{sj}^* = \log(\hat{c}_{cj}) + \log(\tilde{\eta}_s/(1 + \tilde{\eta}_s))$. Since our observed price measure is standardized, we standardize the optimal prices as well by subtracting the average observed log price in a year-product cell. We then average this standardized optimal price across the products j and further across all stores s at a particular income level. Note that the extent to which the price-income gradient increases in the counterfactual depends both on how much steeper the within-chain pricing slope becomes and on the extent to which low-income

and high-income areas are served by distinct chains.

Figure 10a shows the result for food stores. Areas with higher income have higher actual prices: an extra \$10,000 of local income increases prices on average by about 2 percent. This relationship is consistent with our between-chain relationship (e.g., Table 6 Column 4): chains operating in higher average income areas charge higher prices. Yet, this price-income slope is much flatter than it would be if firms were setting prices optimally. Under flexible pricing, the price increase associated with \$10,000 higher local income would be about 5 percent. The pattern is similar for drugstores (Figure 10b). For mass-merchandise stores, the observed price-income relationship is in fact negatively sloped, due to the fact that of the two major chains, the one operating in higher income areas has lower prices. Even so, the counterfactual price has a positive slope with respect to income.

These patterns have quantitatively important implications for inequality. For the food stores, stores in the lowest income decile pay about 0.7 percent higher prices than they would pay under flexible pricing, but stores in the top decile of income pay about 9.0 percent lower prices than under flexible pricing. Consolidation between retailers could further strengthen this pattern.

6.2 Response to local shocks

A second implication of our findings relates to the response of prices to local economic shocks (Beraja, Hurst, and Ospina, 2016; Stroebel and Vavra, 2015). Benchmark models assume that when a negative shock to income or wealth hits consumers an area, the impact on welfare will be offset to some extent by reductions in local retail prices. Similarly, any shocks that increase local costs would tend to be reflected in higher prices. Our results suggest that such responses will be dampened by uniform pricing, and that this will be more true the smaller the area affected by the shock.

The magnitude of this effect depends on the geographic distribution of stores, as well as the degree of uniform pricing. We provide an illustrative calibration in Table 11. For simplicity, we focus on our benchmark product in the orange juice module. We assume that some group of stores faces a shock to either demand elasticity or marginal cost equivalent to a 10 percent marginal cost increase. We consider in turn each of a set of such shocks that differ in the set of stores affected. These are (i) a national shock that affects all stores in the country; (ii) a set of 48 state-level shocks, each of which affects all stores in a given state; (iii) a set of analogous county-level shocks. For each shock, we compute the response of prices under optimal pricing (Column 1), under uniform pricing (Column 2), and under the estimated pricing (Column 3), similar to what we did in Section 4.5. For the local shocks in groups (ii) and (iii), we report the mean response across shocks in each group.

Table 11 shows that the impact of a national-level shock under all pricing regimes, as well as a state or county-level shock under optimal pricing, is to increase prices by about 10 percent. The responses to local shocks are substantially dampened under both uniform and actual pricing. The average state-level shock produces only a 3 percent increase in prices, and the average county-level

shock produces just a 0.2 percent increase in prices. This reflects the fact that most stores in a given state or county reflect only a small fraction of the total stores in their respective chains.

Panels B and C explore these responses further by considering an example of a cost shock affecting California or Nevada. Given that California is a large state, a 10 percent cost shock in California leads to an increase in prices in the California stores of 7.8 percent, still dampened but much closer to the response under optimal pricing. In contrast, a 10 percent cost shock in Nevada increases the prices in Nevada stores by only 1.9 percent. This example also illustrates potential price spillovers. Under flexible pricing, a 10 percent cost shock in California leaves prices unaffected in Nevada. Under uniform pricing, instead, it causes prices in Nevada to increase by 4.3 percent, as some stores in Nevada are part of the same chains as stores in California. Uniform pricing thus causes not just under-response to local shocks, but also spillover in pricing beyond the region affected by the shock.

6.3 Incidence of trade costs

A third implication of uniform pricing relates to the estimation and incidence of trade costs. A large literature estimates trade costs by examining differences in the prices of specific products at geographically separated retail stores. Prior studies are surveyed by Fackler and Goodwin (2001) and Anderson and van Wincoop (2004). As a recent example, Atkin and Donaldson (2015) use prices in the Nielsen RMS data to estimate trade costs, accounting explicitly for the source locations of the products and the possibility of spatially varying markups.

Setting aside for a moment the adjustment for markups, this strategy will estimate trade costs to be larger the more prices vary across space. Uniform pricing would thus lead trade costs to be underestimated. At an extreme, if all stores were owned by a single chain that practiced uniform pricing, the estimated trade costs would be zero. In the observed data, the extent to which they are underestimated will depend on the size and geographic distribution of chains.

How would uniform pricing affect the adjustments for markups? Atkin and Donaldson (2015) propose an innovative strategy that infers the extent of market power from the observed passthrough of price shocks in origin locations to prices in stores further away. While they would ideally use the origin wholesale price, this is not available in the data so they use the origin retail price as a proxy. Uniform pricing will tend to increase the estimated passthrough, as it increases the correlation between changes in retail prices in the origin with retail prices in other markets with stores from the same chains as the stores in the origin. It will therefore tend to reduce the level of estimated markups, while (correctly) implying less variation in markups across space. The extent of these effects again depends on the size and distribution of chains.

Both of these points relate to the estimation of trade costs. Uniform pricing also affects the true incidence of these costs. Just as we noted above that uniform pricing tends to raise prices in high-income areas and lower them in low-income areas, so too here it will tend to raise prices in

locations close to where products are produced and lower them in remote locations. It thus shifts the incidence of trade costs away from those who actually purchase transported goods and toward those whose goods travel shorter distances.

7 Conclusion

In this paper, we show that most large US grocery and drug-store chains in fact set uniform or nearly-uniform prices across their stores. We show that limiting price discrimination in this way costs firms significant short-term profits. We find managerial costs to be the most plausible explanation for this pattern. We show that the result of nearly-uniform pricing is a significant dampening of price adjustment, and that this has important implications for the extent of inequality, the pass-through of local shocks, and the incidence of trade costs.

A Appendix

A.1 Data

A.1.1 Store Selection.

In the RMS data, Nielsen provides a basic categorization of stores into five “Channel Codes”: Convenience, Food, Drug, Mass-Merchandiser, and Liquor. Of these, we select Food, Drug, and Mass-Merchandise chains since the Convenience and Liquor stores are typically not covered in the HMS data and thus would not be included in our final sample. In the HMS data, there are more detailed “Retailer Channel Codes” and each store is assigned to one of 66 mutually exclusive categories such as Department Store, Grocery, Fruit Stand, Sporting Goods, and Warehouse Club. Our starting sample of food stores includes all stores that are categorized as “Food” stores in the RMS data. All the food stores selected in the final sample fall into the “Grocery” store category in the HMS channel code categorization⁴¹, the drugstores are all “Drug Stores,” and the Mass-Merchandise stores are all “Discounters.”

Some stores change DMA or FIPS code over the time that they are in the sample. Since Nielsen identifies store by the physical location of the store, this occurs because DMA regions or county lines are redefined over the nine years we observe. In other words, the stores themselves are not changing physical locations. For stores that switch, we use the modal DMA and FIPS code. This does not affect how we aggregate store-level demographics for our main analysis.

A.1.2 Demographics

All demographics are zip-code level data from the 2008-2012 5-year ACS. We aggregate this zip-code level demographics into store-level demographics as explained in Section 2. There are two special cases: (i) for one store with missing median home price data, we impute this value by regressing median home price on the other demographics (income, fraction with a bachelor’s degree, race, and percent urban); (ii) three drugstores are only visited by one household each, and these households provide a PO Box zip code as its zip code, making it impossible to use our usual procedure; we use county-level demographics for these three stores.

A.1.3 Competition Measures

We use the HMS panel data to help us construct a measure of competition based on geodesic distance. To compute the location of each store, we use the more detailed location information in the HMS data.⁴² First, we assume that each HMS household lives at the center of its zip code. For each of the stores in the HMS dataset, we use a trip-weighted average of the coordinates of each household in order to arrive at an imputed location for the store. For our measure of competition for store s , we then count the number of stores of the same channel (e.g., food stores, counting only other food stores) within various distances (e.g., 5 or 10 km) of store s by geodesic distance.⁴³

A.1.4 Product selection

We select 10 modules (product categories) based on commonly available and highly-sold products in food stores. These products include five that belong to product groups used in Hoch et al. (1995) (soup, cookies, orange juice, soda, and toilet paper) and in Montgomery (1997) (orange juice).

⁴¹The starting sample of 11,501 Food stores also contains some Discount Stores and Warehouse Clubs, as well as some (likely mislabeled) drugstores.

⁴²Recall that the location of the store in the Nielsen publicly available data is only recorded up to the 3-digit zipcode or county.

⁴³i.e. distance as the crow flies

Within a module (e.g., soda), we select a high-selling product (e.g., 12-pack cans of Coke). The product choice aims to ensure that (i) the product is available across as many chains and stores as possible (to ensure comparability across stores and across chains), and that (ii) within a store, it is sold in as many weeks of the year as possible (since otherwise the price is not recorded). We select the product within a module-year with the highest number of week-store observations with positive sales. This procedure typically selects, for a given module, different products in different years. We refine this initial selection with an eye to identifying a constant product across all 9 years, when possible. We search for a single product (UPC) that is present in all nine years and with availability in each module-year at most 10 percentage points below that of the top product. In food stores, this leads us to identify a consistent product for 7 out of 10 modules; for the remaining 3 modules, the selected product varies across the years. Because of low availability, we identify two constant products in drugstores⁴⁴ and five products in mass-merchandise stores, two of which are constant.

For robustness analysis, just for the food stores, we also identify an additional set of four products. (i) (*Less Commonly Sold Items*) For each module, we also select the 20th-highest availability seller (for example, 6 oz Chobani Black Cherry); this product is chosen to be the same across all chains. (ii) (*High-quality products*) Since high-quality, high-price products are not well represented in our benchmark products, for three modules (chocolate, cookies, and coffee) we identify products that are in the top 2 quintiles of average price (conditional on package size) and are high in availability, as defined above. We select three coffee products (for example, Starbucks 12 oz French Roast), 3 cookie products (Pepperage Farm Chessmen), and 2 chocolate product (Lindt 5.1 oz bar). (iii) (*Chain-specific generic product*) We identify within each module a generic (store-brand) product as the product with highest availability within each chain among the UPCs with the Nielsen identifier “CTL BR” (which identifies store-brand products). This generic product is not comparable across chains. (ii) (*Generic product across chains*) We choose a different set of generic products to enable between-chain comparisons. We take advantage of the fact that Nielsen assigns the same (masked) UPC to products it deems similar across chains, e.g. “Yogurt 32 oz.” To minimize the chance that we identify non-comparable products across chains, we require that the average price for each store-product is within 20% of each other for stores in the same DMA. On this sample of products, we apply a similar product selection procedure as for our benchmark products, leading to generic products that are comparable across (most) chains for 4 modules (soup, cookies, soda, and yogurt).⁴⁵

A.1.5 Prices.

As described in the text, we compute the weekly price P_{sjt} as the ratio of weekly revenue and weekly units sold for that store-product. We apply the following filters: (i) Following the Nielsen manual, we divide the weekly units sold by the variable ‘prmult’ (price multiplier); (ii) We drop all prices \leq \$0.10 since almost surely these represent cases of measurement error. This affects very few observations: 1,298 store-product-weeks (0.003% of observations) in food stores, 1,613 observations (0.017%) in drugstores, and 459 observations (0.006%) in mass-merchandise stores.

A.1.6 Pairs Dataset for the Analysis of Store Pricing Similarity

For the measure of similarity in pricing across stores, we create a data set of pairs of stores. For the within-chain comparisons, we select up to 200 stores per chain, out of which we form all possible pairs. For the chains with more than 200 stores, we select 200 stores with consistent presence in the sample, since we could not compare the similarity in pricing between stores operating in different sample years. (Recall that the condition for inclusion of a store is data availability for at least 104

⁴⁴In drugstores, we replace the top-availability soda UPC with the fifth-highest-availability soda UPC as the top four products go on temporary price reductions extremely rarely and thus make it difficult to identify the demand elasticity.

⁴⁵For each store, we keep only the generic modules with at least 80% availability over the 9 years. Some stores have pricing information for only a subset of the 4 generic products.

weeks). Specifically, we select stores with non missing price observations for at least 60% of the 468 sample weeks in at least 5 out of 10 modules in food stores, 1 out of 2 modules for drugstores, and 3 out of 5 modules for mass-merchandise stores. For the between-chain comparisons, given that some of the comparisons condition on DMA, we sample one store per chain-DMA if there are multiple chains in a DMA and two stores per chain-DMA otherwise.

For the between-chain sample, we begin with the within-chain sample (limited to a maximum of 200 stores per chain) and select the maximum of 1 store or 7.5% of stores (rounded down) in that sample, giving preference to stores with consistent presence in the sample as described above.

A.1.7 Major Grocer Data

As additional data, we use the scanner data for 250 stores from a major grocer as in Gopinath et al. (2011). Since we want to compare the results using the Nielsen price measure versus the price measures in this major grocer data, it is important to identify the stores in the Nielsen data which correspond to stores in this additional data set. Since the dataset in Gopinath et al. (2011) covers 2004 to mid-2007, we focus on the 1.5 years of overlap covering all of 2006 and part of 2007. We match the two data sets using the 3-digit zip code and (with a fuzzy match) using the sum of units sold in 2006 for our benchmark products in the 10 modules. This results in 132 matches to stores in our main sample, all of which belong to a single Nielsen retailer_code. We validate the correctness of the matches using data on price and with an alternative matching algorithm.

A.1.8 Imputing Nonsale Prices from Nielsen RMS Data

The major grocer data provides information on non-sale prices. While we do not have the same information in the Nielsen RMS dataset, we infer non-sale prices using the following procedure. We keep only prices that are above the 80th percentile of prices in a given store-year-module. Further, we require that a given price is charged for 3 weeks in a row (two weeks in a row for the first and last weeks of each year). This yields $P_{s jt}^{nonsale}$ for the weeks t where this variable is defined. We then calculate the price level as detailed in Section 2. For the 132 stores that are both in the Nielsen and in the major grocer data, we can provide a validation of this procedure comparing the non-sale price measure computed this way with the non-sale price variable in the major grocer data. The two data series match perfectly for all but 13 store-product-weeks.

Figure 1. Examples of *Uniform Pricing*

Figure 1a. Pricing for Chain 128, Orange Juice

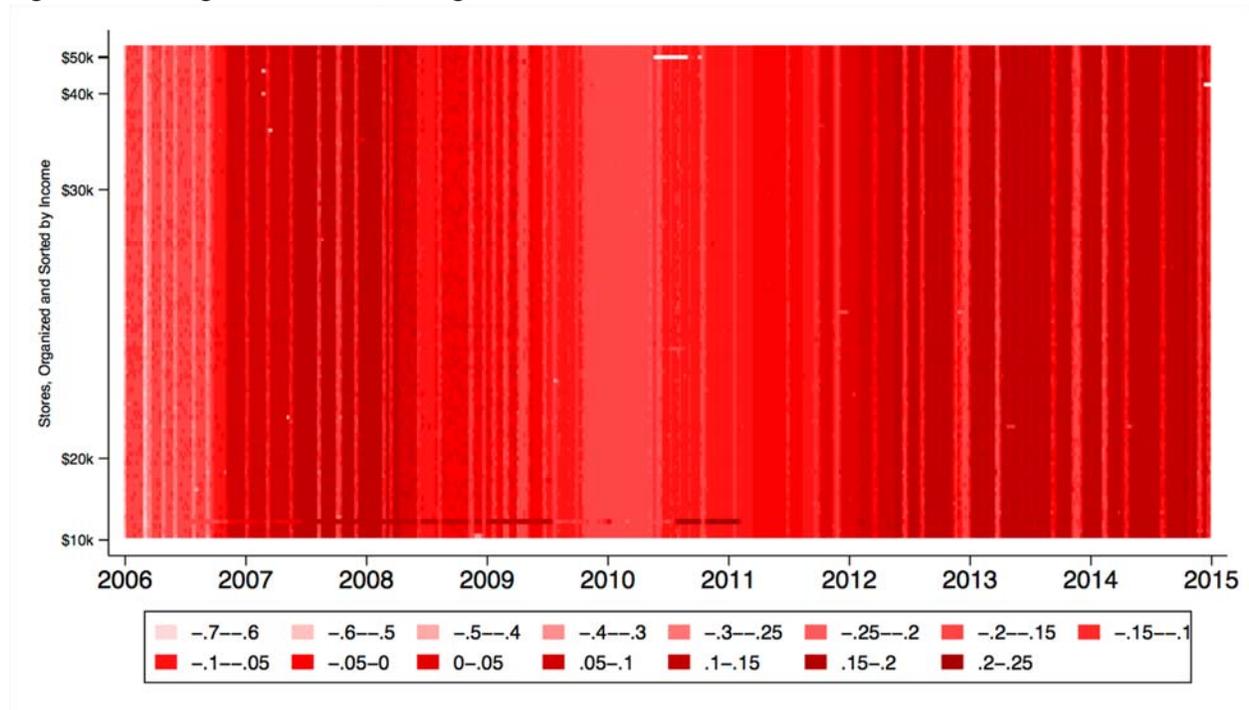

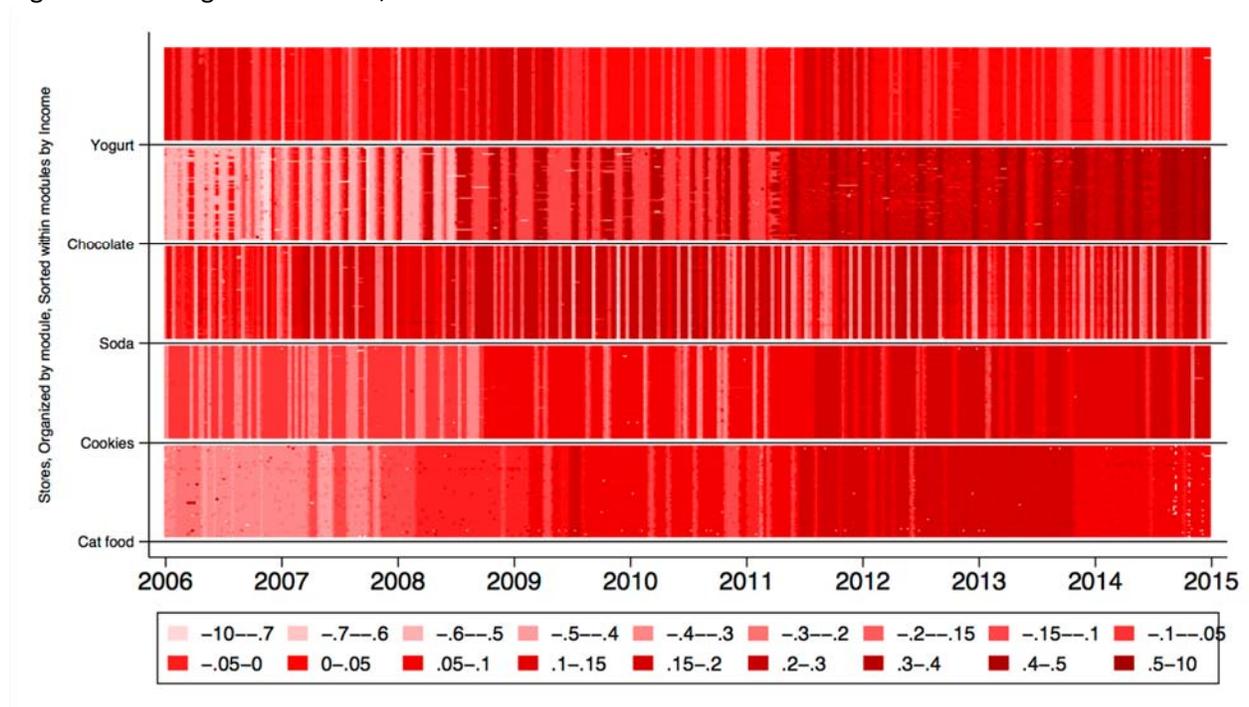

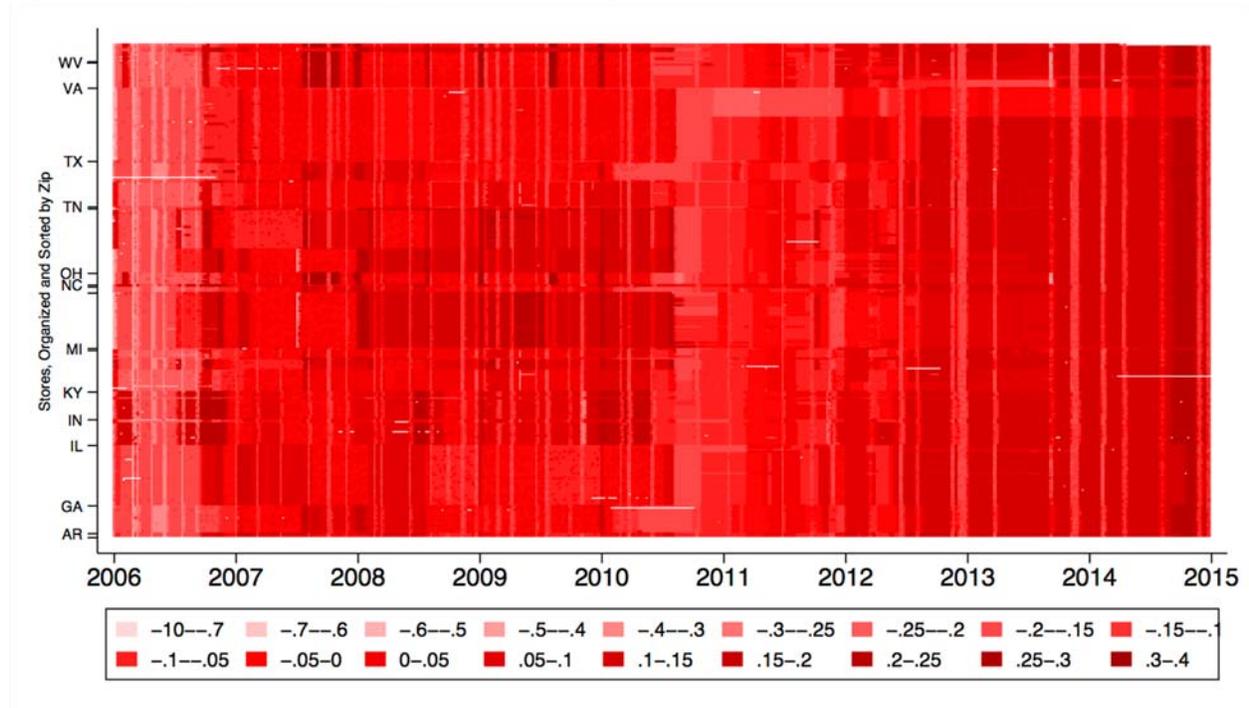

Figure 1b. Pricing for Chain 128, 5 Different Products

Notes: Plots depict log price in store s and week t for a particular product j . To facilitate comparison across products, we standardize prices by demeaning the log price by the average log price across all stores s in all chains, within a year. Thus, a log price of 0.1 indicates a price that is 0.1 log points higher than on average. Darker colors indicate higher price and are blank if price is missing. Each column is a week. Each row is a store, and stores are sorted by store-level income per capita. In Figure 1a, dividers are \$10,000s differences in the per-capita income measure. In Figure 1b, the same 50 stores appear for each product.

Figure 2. Example of *Zone Pricing*: Chain 130, Orange Juice

Notes: Plots depict demeaned log prices, same as in Figure 1. The only difference is that stores are not sorted by per-capita income (as in Figure 1) but are instead sorted first by state and then by the three-digit zip code of the store within each state.

Figure 3. Similarity in Pricing Across Stores: Same-Chain comparisons versus Different-Chain Comparisons.

Figure 3a. Quarterly absolute difference in log prices

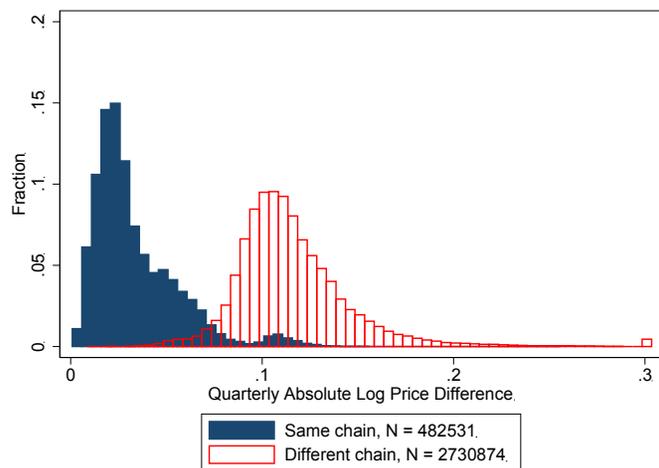

Figure 3b. Weekly correlation of log prices

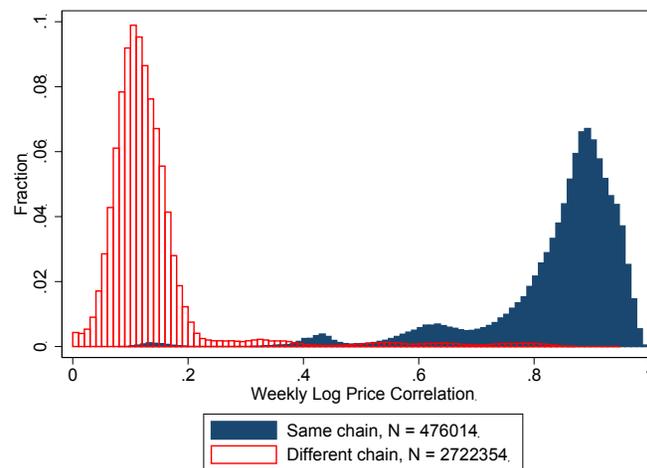

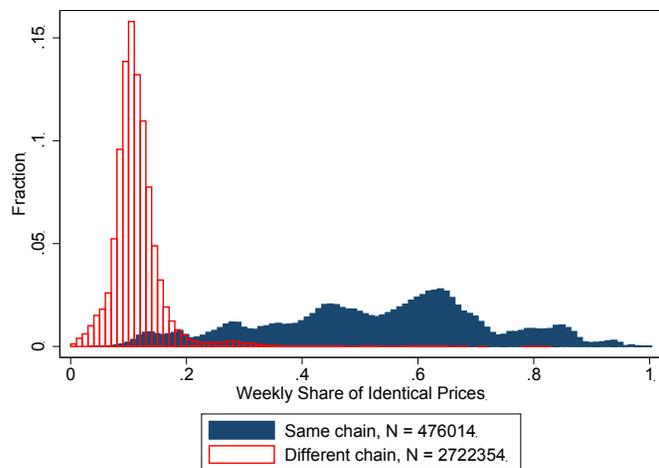

Figure 3c. Share of Identical Prices

Notes: Each observation in the histograms is a pair of stores. The “same chain” pairs are formed from stores belong to the same chain; the “different chain” pairs are formed from stores in different chains, requiring in addition that the two stores do not belong to the same parent_code. Figure 3a displays the distribution of the average absolute difference in log(quarterly prices) between two stores in a pair, Winsorized at 0.3. Figure 3b displays the distribution of the correlation in the weekly (demeaned) log prices between two stores, winsorized at 0. Figure 3c displays the share of prices in a pair of stores that are within 1 percent of each other. A maximum of 200 stores per chain are used for the same-chain pairs to bound the overweighting of the 10 largest chains. See Appendix Section A.1.4 for details on how we formed the different-chain pairs.

Figure 4. Similarity in pricing, Chain-Level Measure

Figure 4a. Quarterly Similarity in Pricing versus Weekly Correlation of Prices, by Chain

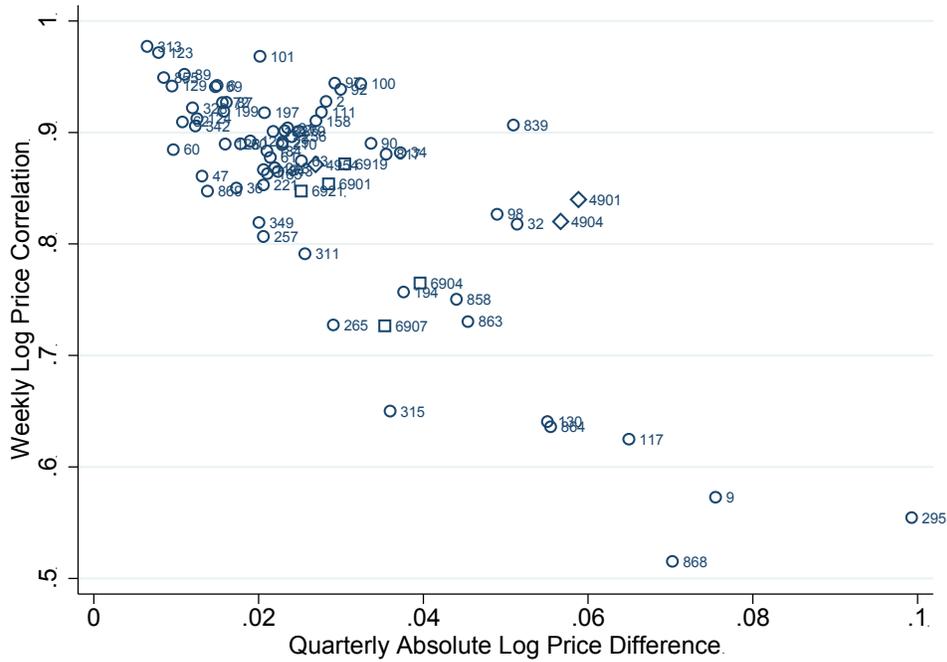

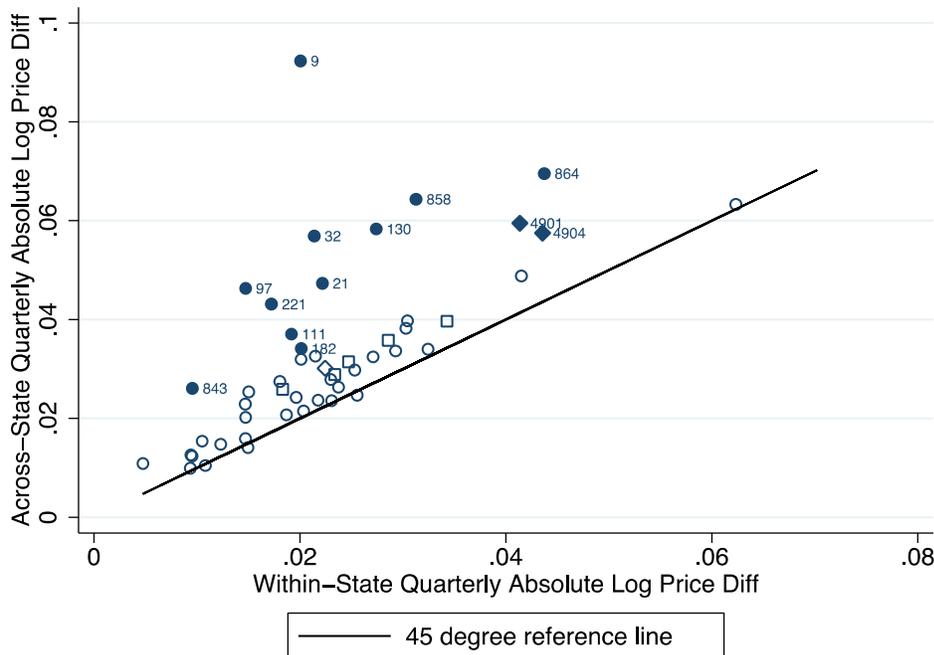

Figure 4b. Within-State Price vs Between-State Price Quarterly Absolute Log Price Difference by Chain

Notes: Each observation in Figures 4a-b is a chain, with circles representing food stores, diamonds representing drugstores, and squares representing mass-merchandise stores. In Figure 4a for each chain we plot the average across all within-chain pairs of the quarterly absolute difference in log price (Figure 3a) and of the weekly correlation in log price (Figure 3b). We compute the averages using up to 400 stores within a chain; for chains with over 400 stores, we select randomly among the stores with data for the maximum number of weeks. In Figure 4b, each observation is a chain that operates at least three stores in multiple states. Chains that differentiate pricing geographically—difference between across-state and within-state quarterly absolute price difference greater than .013—are labeled.

Figure 6. Zone Pricing

Figure 6a. Food Stores (Non-Zone-Pricing Chains Only), State Zones

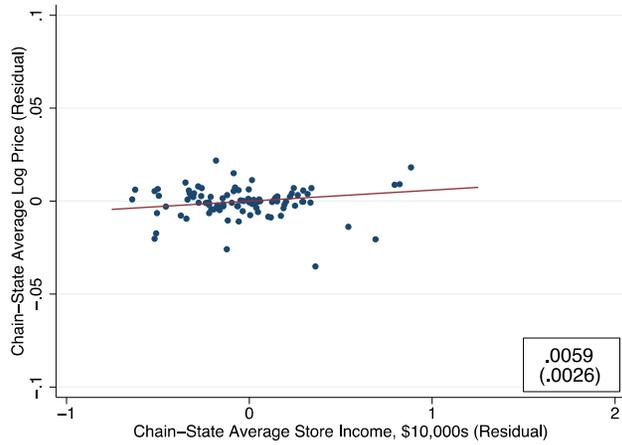

Figure 6b. Food Stores (Zone Pricing Chains), State Zones

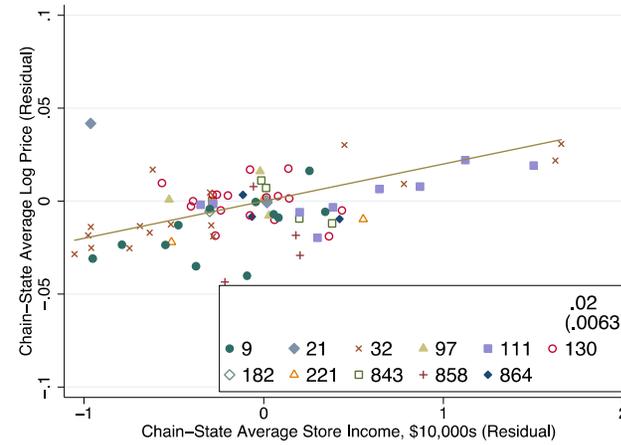

Figure 6c. Drug Stores, State Zones

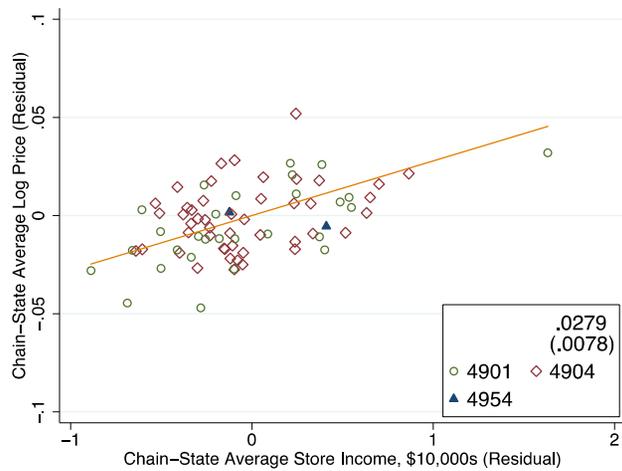

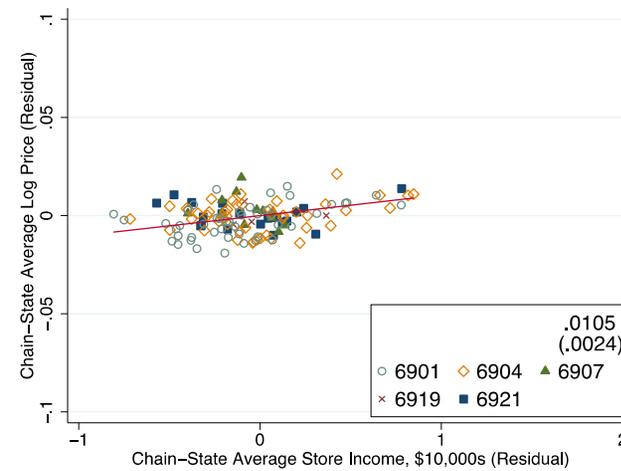

Figure 6d. Mass Merchandise Stores, State Zones

Notes: Figures 6a-d are scatters of the chain-state averages of log price and income, demeaned by chain. Figure 6a displays this for the Food stores that operate in multiple states and do not price by state zones (that is, is not labelled in Figure 4b); the figure does not display one chain-state outlier with income residual of \$30,800. Figures 6b,c,d denote each chain with different shapes and colors. Figure 6b plots the 10 Food chains identified as zone pricers from Figure 4b. Figures 6c and 6d plots, respectively, the drug stores and mass merchandise stores. Standard Errors are clustered by parent_code* state.

Figure 7. Price Response to Income: Investigation using Major Grocer Data

Figure 7a. Nielsen Data: Average Weekly Price

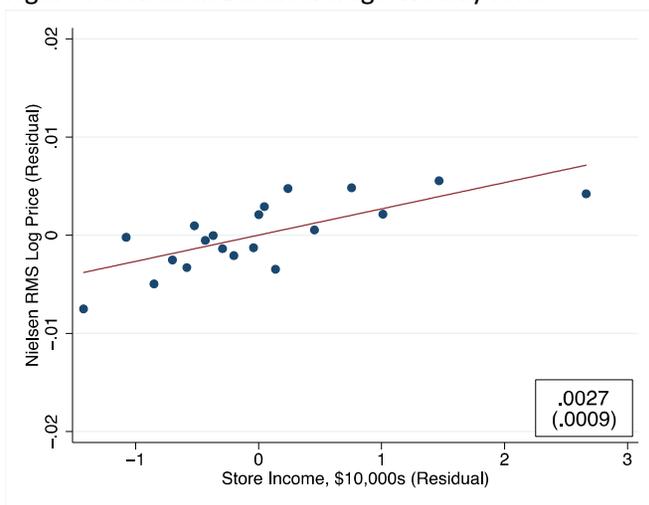

Figure 7b. Data from Major Grocer: Average weekly price

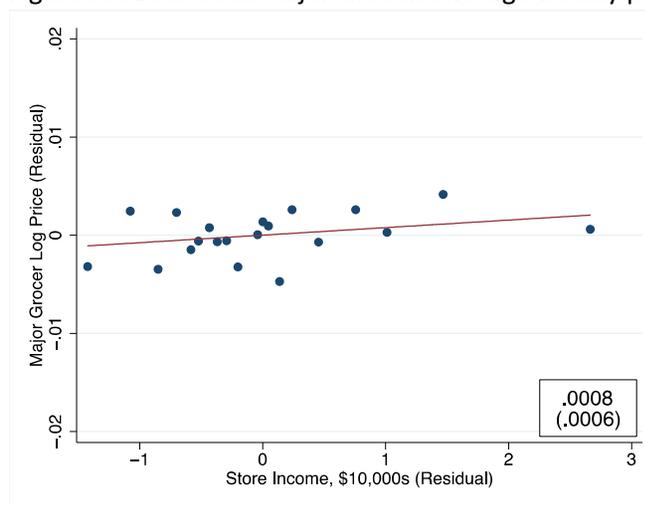

Figure 7c. Data from Major Grocer: Nonsale Price

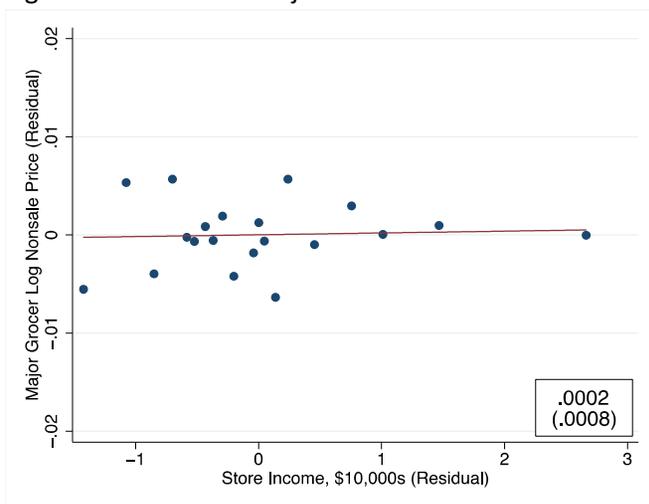

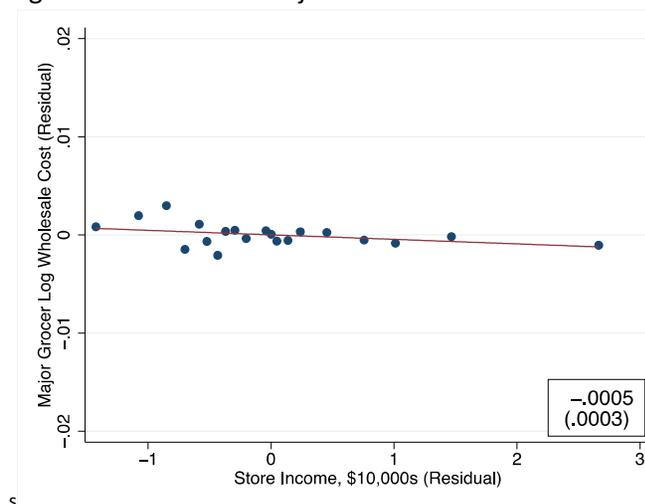

Figure 7d. Data from Major Grocer: Wholesale Cost

Notes: We match 132 stores in our Nielsen sample to stores in the sample of a major grocer (Gopinath et al., 2011). Figure 7a plots a bin scatter with 20 bins of residuals of log price and income for the 132 stores in the Nielsen data, after taking out state fixed effects. The prices in this regression are based on 2006 prices only and are thus not identical to our benchmark price level. Figures 7b-c plot the same bin scatter but using the 2006 price variable from the major grocer data (Figure 7b) and the non-sale price variable from the grocer data (Figure 7c). Figure 7d plots a bin scatter of wholesale cost from the grocer data, again after taking out state fixed effects. The cost variable does not include transport or storage costs and is before supplier discounts. Robust standard errors are used.

Figure 8. Elasticity Estimates and Validation

Figure 8a. Elasticity Estimates

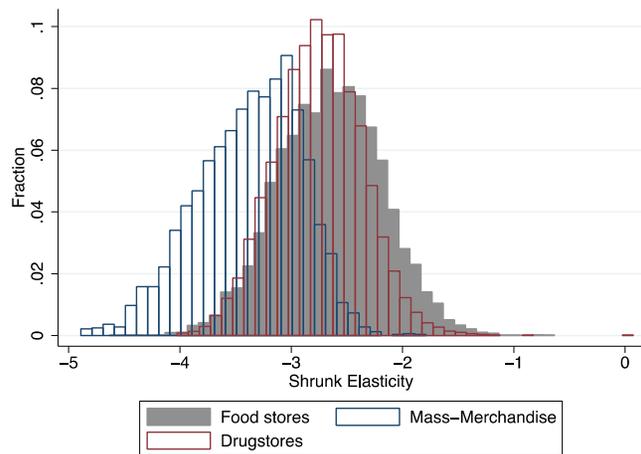

Figure 8b. Elasticity Estimates: Distribution of Standard Errors

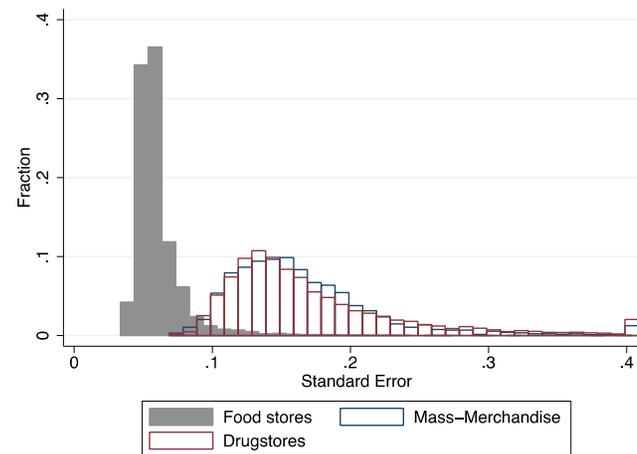

Figure 8c. Validation I. Linearity of Log Q and Log P

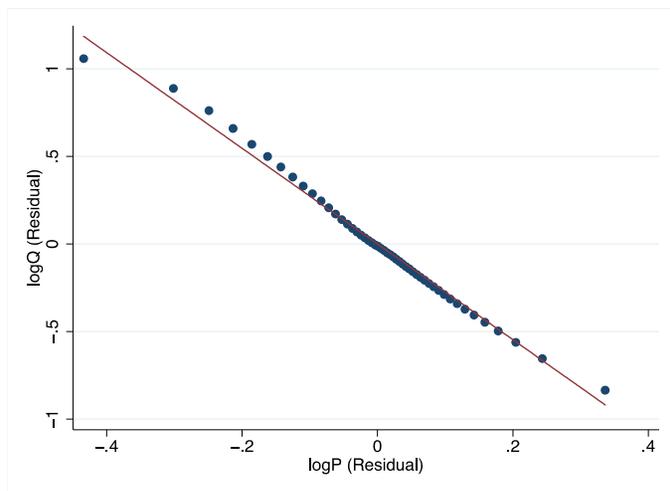

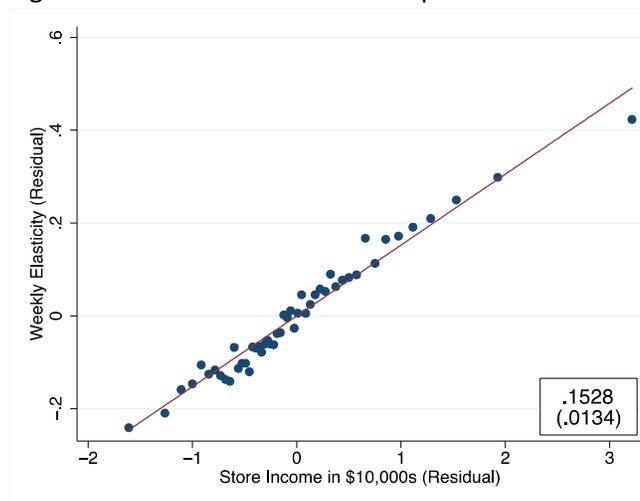

Figure 8d. Validation II. Relationship with store-level income

Notes: Figure 8a plots the distribution of the estimated elasticity at the store level from a regression of log P on log Q with controls for week-of-year and year. The estimates are then shrunk with an empirical shrinkage procedure; see the text for details. Figure 8b plots the distribution of the standard errors of the elasticity, from the regression before the shrinkage adjustment. Figure 8c plots a bin scatter with 50 bins representing 60,552,601 store-module-weeks of log Q on log P, after taking out module*week-of-year and module*year FE. Figure 8d plots a bin scatter with 50 bins of representing 22,680 stores of the elasticity on the store-level income, after residualizing the Chain FE. Standard errors are clustered by parent_code.

Figure 9. Elasticity versus Price, Instrumenting with Income, First Stage

Figure 9a. First Stage, Income and Elasticity within chains

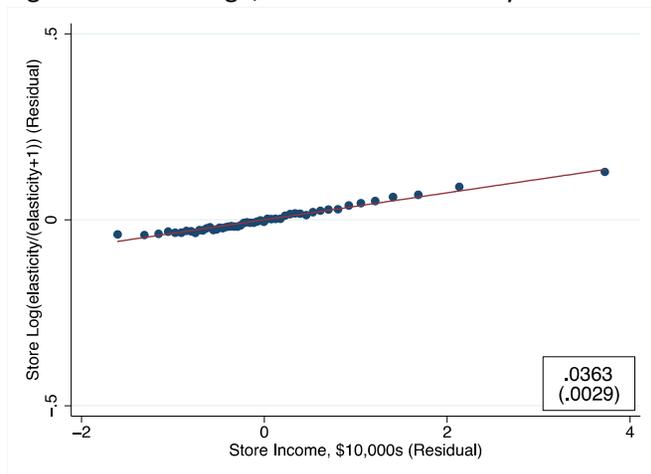

Fig. 9b. First Stage, Between Retailer (Food stores only)

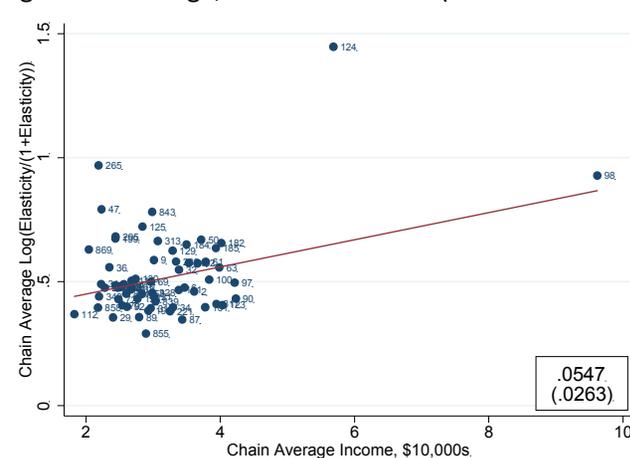

Figure 9c. First Stage, within chain-state

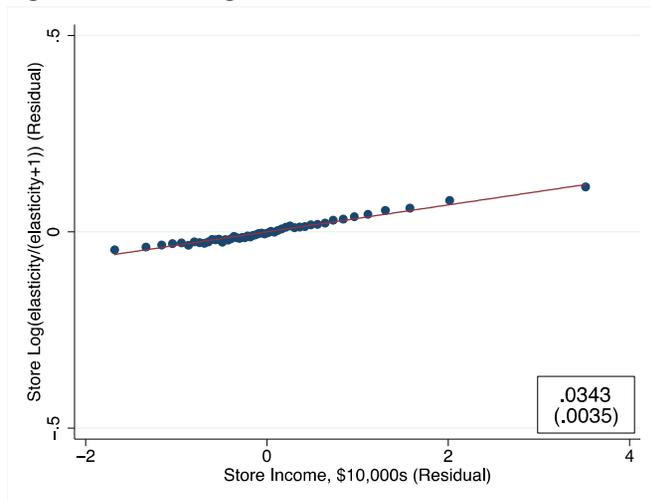

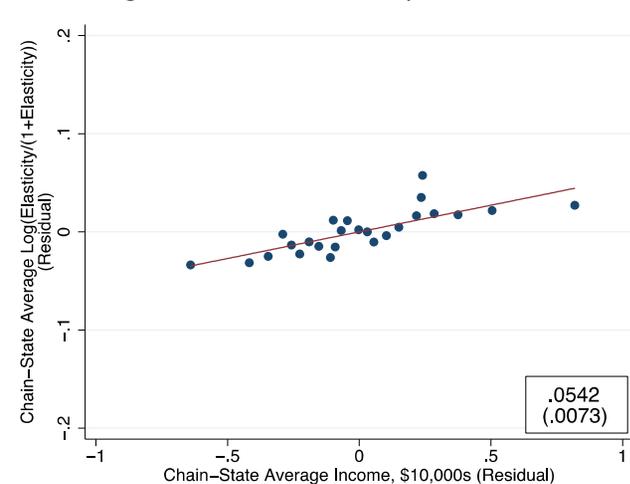

Figure 9d. First Stage, Income and Elasticity, Between Chain-State Averages

Notes: Figure 9a-c plot bin scatters with 50 bins of the residual of $\log(\text{elasticity}/(\text{elasticity}+1))$ in store s on the residual of income in store s . Residuals are after removing Chain FE (Figure 9a) and ChainXState FE (Figure 9c). Figure 9b plots a scatter of average $\log(\text{elasticity}/(\text{elasticity}+1))$ on average income at the chain level, with the labels indicating a chain identifier. Figure 9d plots a bin scatter with 25 bins of chain-state averages of both $\log(\text{elasticity}/(\text{elasticity}+1))$ and income. The figures report the coefficient of the relevant regressions, with standard errors clustered by parent_code. Axes ranges have been chosen to make the slopes visually comparable. Analytic weights equal to the number of stores in each aggregation unit are used for the regression in Figures 9b and 9d.

Figure 10. Price Rigidity and Inequality: Prices in Areas with Different Income.

Figure 10a. Food Stores

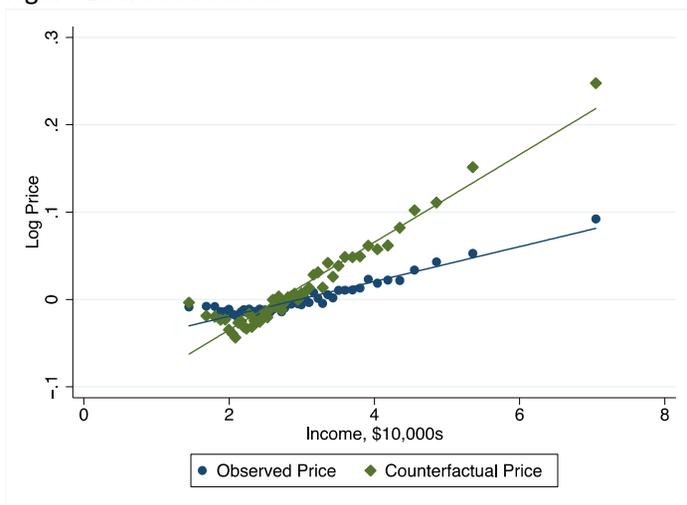

Figure 10b. Drugstores

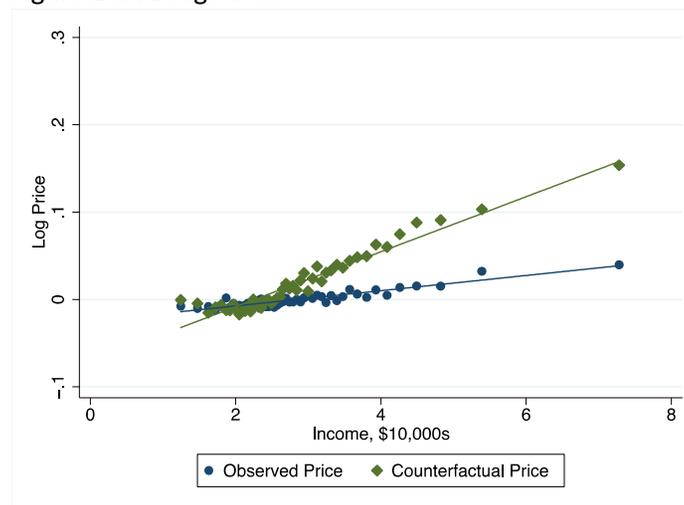

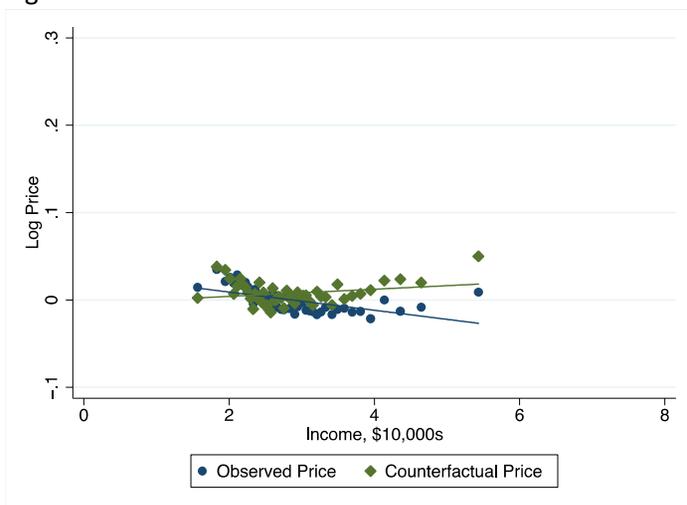

Figure 10c. Mass Merchandise stores

Notes: In these figures, we plot bin scatters with 50 bins of store-level observed log prices and counterfactual log prices (under optimal pricing) versus store-level income. The counterfactual price assumes optimal pricing, that is $\log P^* = \log(\text{elasticity}/(1+\text{elasticity})) + \log(c)$, using the estimated elasticity for each store s and the chain-level marginal costs we have estimated. Prices are standardized using observed prices. Only products constant over time are used.

Table 1. Sample Formation and Summary Statistics: Stores and Chains

	No. of Stores	No. of Chains	No. of States	Total Yearly Revenue	
	(1)	(2)	(3)	(4)	
<i>Panel A. Sample Formation</i>					
Initial Sample of Stores	38,539	326	48+DC	\$224 billion	
Store Restriction 1. Stores do not Switch Chain, >= 104 weeks	24,489	119	48+DC	\$193 billion	
Store Restriction 2. Store in HMS dataset	22,985	113	48+DC	\$192 billion	
Chain Restriction 1. Chain Present for >= 8 years	22,771	83	48+DC	\$191 billion	
Chain Restriction 2. Valid Chain	22,680	73	48+DC	\$191 billion	
Final Sample, Food Stores	9,415	64	48+DC	\$136 billion	
Final Sample, Drug Stores	9,977	4	48+DC	\$21 billion	
Final Sample, Merchandise Stores	3,288	5	48+DC	\$34 billion	
<i>Panel B. Store Characteristics</i>					
	Mean	25th	Median	75th	
Average per-capita Income	\$29,000	\$22,450	\$26,900	\$33,450	
Percent with at least bachelor degree	21.0%	9.3%	17.8%	29.0%	
Number of HMS Households	28.3	11	21	37	
Number of Trips of HMS Households	862	196	502	1162	
Number of Competitors within 5 km	0.8	0	0	1	
Number of Competitors within 10 km	2.7	0	1	3	
<i>Panel C. Chain Characteristics, Food Stores</i>					
	Mean	25th	Median	75th	
Number of Stores	147	30	66	156	
Number of DMAs	7.4	2	4	8	
Number of States	3.4	1	2.5	4	
<i>Panel D. Chain Characteristics, Drugstores</i>					
	Chain 4901	Chain 4904	Chain 4931	Chain 4954	
Number of Stores	3000	6853	55	69	
Number of DMAs	118	201	9	6	
Number of States	32	48+DC	1	2	
<i>Panel E. Chain Charact., Mass-Merchandise Stores</i>					
	Chain 6901	Chain 6904	Chain 6907	Chain 6919	Chain 6921
Number of Stores	1565	1311	138	30	244
Number of DMAs	190	189	36	13	48
Number of States	47+DC	48	13	11	22

Notes: Valid chains are those in which at least 80% of stores with that retailer_code have the same parent_code and in which at least 40% of stores never switch parent_code or retailer_code. Total Yearly Revenue is the yearly average total revenue recorded in the Nielsen RMS dataset.

Table 2. Summary Statistics: Products

		Constant Product	Yearly Product Revenue by Store (in \$)	Weekly Average Price	Weekly Availability
		(1)	(2)	(3)	(4)
<i>Panel A. Product Characteristics, Food Stores</i>					
Canned Soup	(Campbell's Cream of Mushroom 10.75 oz)	Y	\$3,400	\$1.18	99.7%
Cat Food	(Purina Friskies 5.5 oz)	Y	\$450	\$0.49	93.9%
Chocolate	(Hershey's Milk Chocolate Bar 1.55 oz)	Y	\$1,650	\$0.72	99.7%
Coffee		N	\$6,400	\$8.45	96.1%
Cookies	(Little Debbie Nutty Bars 12 oz)	Y	\$2,100	\$1.51	97.3%
Soda	(Coca-Cola 12pk cans)	Y	\$34,100	\$3.99	99.9%
Orange Juice	(Simply Orange 59 oz)	Y	\$5,400	\$3.54	99.1%
Yogurt	(Yoplait Low Fat Strawberry 6 oz)	Y	\$1,900	\$0.64	99.3%
Bleach		N	\$1,950	\$2.04	96.9%
Toilet Paper		N	\$7,000	\$8.60	94.9%
<i>Panel B. Product Characteristics, Drugstores</i>					
Soda	(Coca-Cola 12pk cans)	Y	\$3,600	\$4.30	93.9%
Chocolate	(Hershey's Milk Chocolate Bar 1.5 oz)	Y	\$625	\$0.72	95.7%
<i>Panel C. Product Characteristics, Mass-Merchandise Stores</i>					
Soda	(Coca-Cola 12pk cans)	Y	\$13,300	\$4.12	98.5%
Chocolate	(Hershey's Milk Chocolate Bar 1.55 oz)	Y	\$725	\$0.70	97.9%
Cookies		N	\$2,150	\$2.57	92.9%
Bleach		N	\$2,700	\$2.23	94.6%
Toilet Paper		N	\$7,600	\$8.70	93.2%

Notes: For the Food stores (Panel A) we select ten modules and within each module we identify a product that has high availability (defined as weeks with positive sales) across all stores in all chains, and across weeks. For the 7 modules with Constant Products, the product remains the same across all 9 years and is indicated in parentheses. For the other 3 modules, the product varies year by year, but is nonetheless the same across all chains. For the Drug stores (Panel B) and the Mass-Merchandise stores (Panel C) we follow the same procedure using a subset of modules due to availability issues. The Weekly Average Price is the unweighted average of weekly price observations in all stores. Weekly Availability is number of store-weeks with nonzero sales divided by number of store-weeks in which stores in our sample have positive sales in any products belonging to the 10 modules.

Table 3. Similarity in Pricing Across Grocery Stores, Within-Chain vs. Between-Chain

Measure of Similarity:	Absolute Difference in Log Quarterly Prices		Correlation in (De- Meaned) Weekly Prices		Share of Identical Prices (Up to 1 Percent)	
	Same Chain	Different Chain	Same Chain	Different Chain	Same Chain	Different Chain
Within vs. Between:	(1)	(2)	(3)	(4)	(5)	(6)
<i>Panel A. Benchmark UPCs, All Store Pairs</i>						
Mean	0.034	0.117	0.836	0.128	0.529	0.107
Standard Deviation	(0.023)	(0.034)	(0.127)	(0.106)	(0.189)	(0.048)
Number of Pairs	491,941	2,620,810	490,077	2,616,142	489,901	2,614,537

Number of Pairs	327,457	1,938,276	274,555	1,551,106	274,555	1,551,106

Notes: The table presents measures of similarity of pricing for pairs of stores both within a chain, and across chains. To form the pairs we select a maximum of 200 stores per chain, giving priority to stores that have for at least 7 modules nonmissing data for at least 60% of all quarters with minimum six weeks of nonmissing data (columns (1) and (2)) or 60% of all weeks (Columns (3) - (6)). See Appendix for additional details. In Panel C we compare only pairs of stores in different DMAs and such that one store in the pair is in the bottom third of the income measure, while the other store is in the top third. Between chain comparisons of Generic products (Panel D) are not possible because the generic products selected differ across chains.

Table 4. Determinants of Pricing

Dependent Variable:	Log Prices in Store s				
	(1)	(2)	(3)	(4)	(5)
<i>Panel A. Food Stores</i>					
Own Store Income	0.0175*** (0.0047)	0.0044*** (0.0013)	0.0037*** (0.0009)	0.0029*** (0.0003)	0.0029*** (0.0003)
Chain Average Income		0.0404*** (0.0101)	0.0363*** (0.0109)	0.0284** (0.0129)	
Chain-State Average Income				0.0136* (0.0069)	0.0136* (0.0069)
Fixed Effects			County		Chain
Observations	9,415	9,415	9,415	9,415	9,415
R-squared	0.134	0.290	0.715	0.296	0.925
<i>Panel B. Drugstores</i>					
Own Store Income	0.0084*** (0.0012)			0.0075*** (0.0008)	0.0075*** (0.0008)
Chain-State Average Income				0.0101 (0.0107)	0.0203*** (0.0074)
Fixed Effects					Chain
Observations	9,976			9,976	9,976
R-squared	0.056			0.063	0.469
<i>Panel C. Mass-Merchandise Stores</i>					
Own Store Income	-0.0126*** (0.0031)			0.0029*** (0.0010)	0.0029*** (0.0010)
Chain-State Average Income				-0.0699*** (0.0099)	0.0076*** (0.0019)
Fixed Effects					Chain
Observations	3,288			3,288	3,288
R-squared	0.043			0.272	0.916

Notes: In Panel A, standard errors are clustered by parent_code. In Panels B and C, standard errors are clustered by parent_code*state. In Panels B and C we do not report the specifications with chain-average income given that there are only 4 drug chains and only 5 mass merchandise chains.

R Squared	0.083	0.652	0.670	0.750	0.100	0.697	0.353	0.565
Number of Observations	22,660	22,660	22,660	22,660	22,660	9,415	9,957	3,288

Notes: Standard errors are clustered by parent_code for all columns except for columns (7) and (8), where they are clustered by parent_code*state. All independent variables are our estimate of store-level demographics at the zip-code level based on Nielsen Homescan (HMS) panelists' residences. Demographics are from 2012 ACS 5-year estimates. Fraction with College Degree (or higher) is the fraction of adults 25 and older with at least a bachelor's degree. Controls for Urban Share are a set of dummy variables for Percent Urban for values in [.8, .9], [.9, .95], [.95, .975], [.975, .99], [.99, .999], and [.999, 1]. Columns 6-8 represent the first stage we use in our IV specification (see for example Table 6).

Fixed Effect for Chain-State		X		
Number of Observations	3,288	3,288	142	

Notes: Table 6 reports the results of instrumental variable regressions, in which the log elasticity term ($\log(\text{Elasticity}/(1+\text{Elasticity}))$) is instrumented with store-level income as in Table 5, Columns 5-8. The standard errors are block bootstrapped. In Panel A, bootstrap clusters are parent_codes. In Panels B and C, bootstrap clusters are parent_code*state. Elasticities are Winsorized to -1.2. In Columns 3 and 4, the means are average log elasticity term (not Log of average elasticity). In Panels B and C we do not report the Between-Chain results in column(4) given that there are only 4 drug chains and only 5 mass merchandise chains.

Fixed Effect for Chain*State		X		
Number of Observations	9,296	9,296	171	61

Notes: The table reports the results for the sample of food stores of instrumental variable regressions, in which the log elasticity term (log(Elasticity)/(1+Elasticity)) is instrumented with store-level income. The standard errors are block bootstrapped by parent_code. Elasticities are Winsorized to -1.2. Panels A and B use, respectively, quarterly elasticity and our index elasticity instead of the benchmark elasticity and the first stage is as in Online Appendix Table 4 columns 7-8. These panels do not have the full sample of 9,415 stores because we excluded stores that had elasticity estimates with large standard errors and estimates greater than zero. Panel A uses weekly average prices as the dependent variable, while Panel B uses the average of the weekly price index values. Panel C uses a richer set of regressors for the first stage and the benchmark weekly price; see Online Appendix Table 4 Column 6. Panels D uses the benchmark elasticity but using the price for a panel of generic products as the dependent variable. Panel D does not have the full sample because not all stores sell a generic product that we have deemed comparable.

*** p<0.01, ** p<0.05, * p<0.1

Table 8. Average Weekly Price vs. Average Yearly Price (Food Stores)

Dependent Variable:	Log Prices in Store <i>s</i>		Average Log Price for Chain-State	Average Log Prices for Chain <i>c</i>
			Between-Chain-State, IV	Between-Chain, IV
Specification:	Within-Chain, IV			
	(1)	(2)	(3)	(4)
<i>Panel A. Price Variable is Average Weekly Log Price (Benchmark)</i>				
Log (Elast. / (Elast.+1)) in Store <i>s</i>	0.0919*** (0.0339)	0.0605*** (0.0100)		
Mean Log (Elast. / (Elast.+1)) in State-Chain Combination			0.351* (0.202)	
Mean Log (Elast. / (Elast.+1)) in Chain <i>c</i>				0.936*** (0.196)
Fixed Effect for Chain	X		X	
Fixed Effect for Chain*State		X		
Number of Observations	9,415	9,415	171	64
<i>Panel B. Price Variable is Log of Average Yearly Price</i>				
Log (Elast. / (Elast.+1)) in Store <i>s</i>	0.223*** (0.0316)	0.193*** (0.0142)		
Mean Log (Elast. / (Elast.+1)) in State-Chain Combination			0.479*** (0.154)	
Mean Log (Elast. / (Elast.+1)) in Chain <i>c</i>				0.979*** (0.239)
Fixed Effect for Chain	X		X	
Fixed Effect for Chain*State		X		
Number of Observations	9,415	9,415	171	64

Notes: The price variable in Panel B is computed as our benchmark (Panel A), except that we take the ratio of yearly revenue to yearly units sold, instead of taking the ratio at the weekly level. Standard errors are block bootstrapped at the parent_code level. Elasticities are Winsorized at -1.2. The sample is restricted to food stores. The first stage uses within-chain variation in income and log(elasticity/(elasticity+1)) as in Table 5 Column 6.

*** p<0.01, ** p<0.05, * p<0.1

Table 9. Estimated Loss of Profits

	Mean	10th	25th	Median	75th	90th
<i>Panel A. Store-Level (N=22,678)</i>						
Loss of Profits Comparing Optimal Pricing to Uniform Pricing	8.90%	0.11%	0.74%	3.47%	10.56%	23.00%
Loss of Profits Comparing Optimal Pricing to Actual Price-Elasticity Slope	6.51%	0.08%	0.54%	2.54%	7.68%	16.70%
Loss of Profits Comparing Optimal Pricing to State-Zone Optimal Pricing	7.19%	0.09%	0.54%	2.49%	7.97%	18.50%
	Mean	10th	25th	Median	75th	90th
<i>Panel B. Chain-Level (N=73)</i>						
Loss of Profits Comparing Optimal Pricing to Uniform Pricing	8.73%	2.90%	4.89%	6.93%	9.85%	16.03%
Loss of Profits Comparing Optimal Pricing to Actual Price-Elasticity Slope	6.91%	2.09%	3.93%	5.63%	7.45%	12.14%
Loss of Profits Comparing Optimal Pricing to State-Zone Optimal Pricing	6.96%	2.15%	3.87%	6.08%	8.18%	12.77%

Notes: The Table reports the difference between the profits computed under optimal pricing and the profits under alternative scenarios, divided by the profits under optimal pricing. Optimal pricing is assuming the monopolistic competition model and thus deriving optimal prices using $\log(p)=\log(\text{elas.}/(1+\text{elast.})) + \log(c)$, with the estimated store-level elasticities (Winsorised at -1.2). Uniform pricing assumes that each chain responds sets the optimal uniform price across its stores. Pricing according to the actual price-elasticity slope assumes that chains set prices according to $\log(p)=\beta\log(\text{elas.}/(1+\text{elast.})) + \log(c)$, where β is the IV estimate in Table 6, Column 1. State-Zone Optimal Pricing assumes that the chain charges a uniform price within each state, with the price set optimally in the chain-state. In Panel A each observation is a store. In Panel B we aggregate to the chain level.

Table 10. Determinants of Flexible Pricing

Dependent Variable:	Price-Elasticity Relationship (IV) for Chain <i>c</i>				
	(1)	(2)	(3)	(4)	(5)
Log (No. of Stores)	0.0229** (0.0087)	0.0039 (0.0093)			0.0044 (0.0227)
Log (No. of States)	-0.0334** (0.0163)	-0.0358** (0.0150)			-0.0408 (0.0272)
Log (Average Yearly Store Sales)	0.0125* (0.0068)	0.0341*** (0.0081)			0.0312*** (0.0108)
Standard Deviation of Store-level Per-capita Income		0.124*** (0.0285)			0.1443*** (0.0401)
Log Dollar Profit Loss from Uniform Pricing			0.0393*** (0.0134)		-0.0001 (0.0233)
Percent Profit Loss from Uniform Pricing			-0.0014 (0.0029)		-0.0023 (0.0038)
Share of Stores with Competitor Stores within 10 km				-0.0618 (0.0966)	-0.0011 (0.0349)
Share of Store with Same-Chain Stores within 10 km				-0.0128 (0.0876)	-0.0177 (0.0627)
Analytic Weights	Y	Y	Y	Y	Y
Number of observations	73	73	73	73	73
R-squared	0.548	0.662	0.300	0.043	0.670

Notes: The dependent variable is the chain-by-chain estimate of the IV specification, as in Column 1 of Table 6, computing the first stage using all chains. Standard errors are clustered by parent_code. Analytic weights equal to the inverse standard error squared of the reduced form chain-level regression of price on income are used. The chain-level percent profit loss from uniform pricing is as in Table 9, Panel B, row 1. The log dollar profit loss from uniform pricing is computed taking the store-level loss from uniform pricing in dollar terms, and scaling it up by the share of revenue in that store due to the selected UPCs; we then sum the dollar losses across stores in a chain, and take the log.

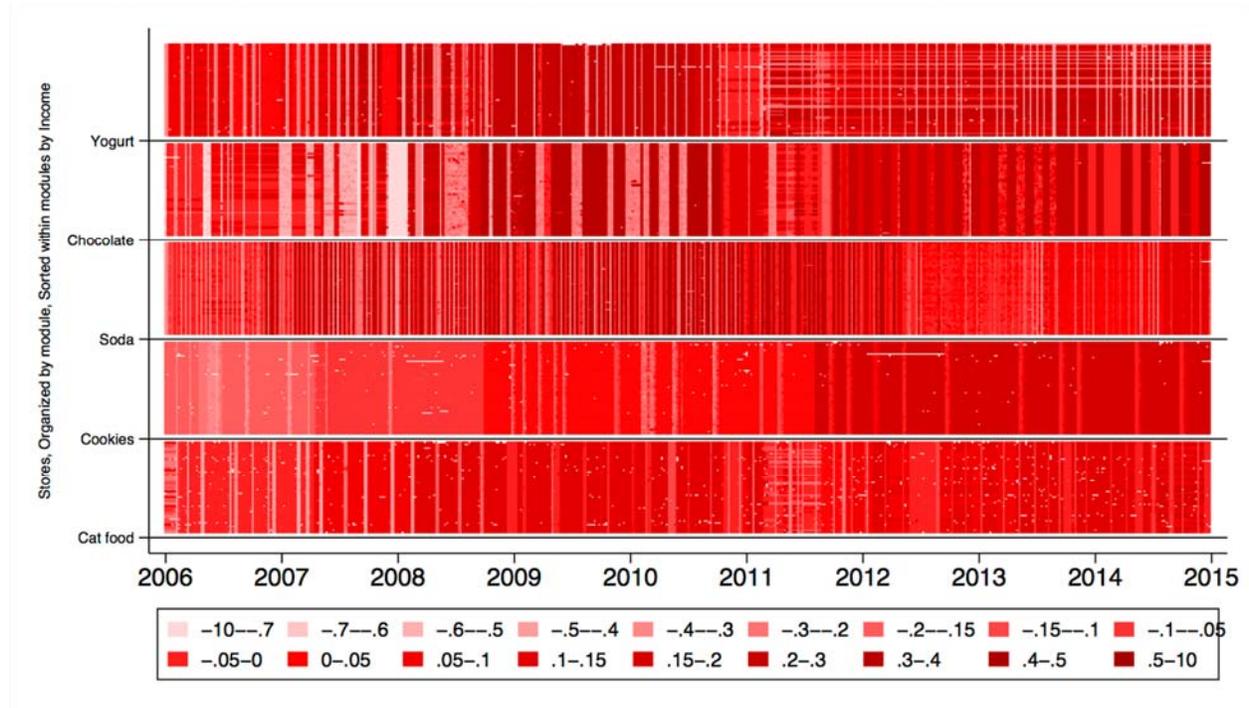

*** p<0.01, ** p<0.05, * p<0.1

Table 11. Macro Shocks Under Uniform Pricing

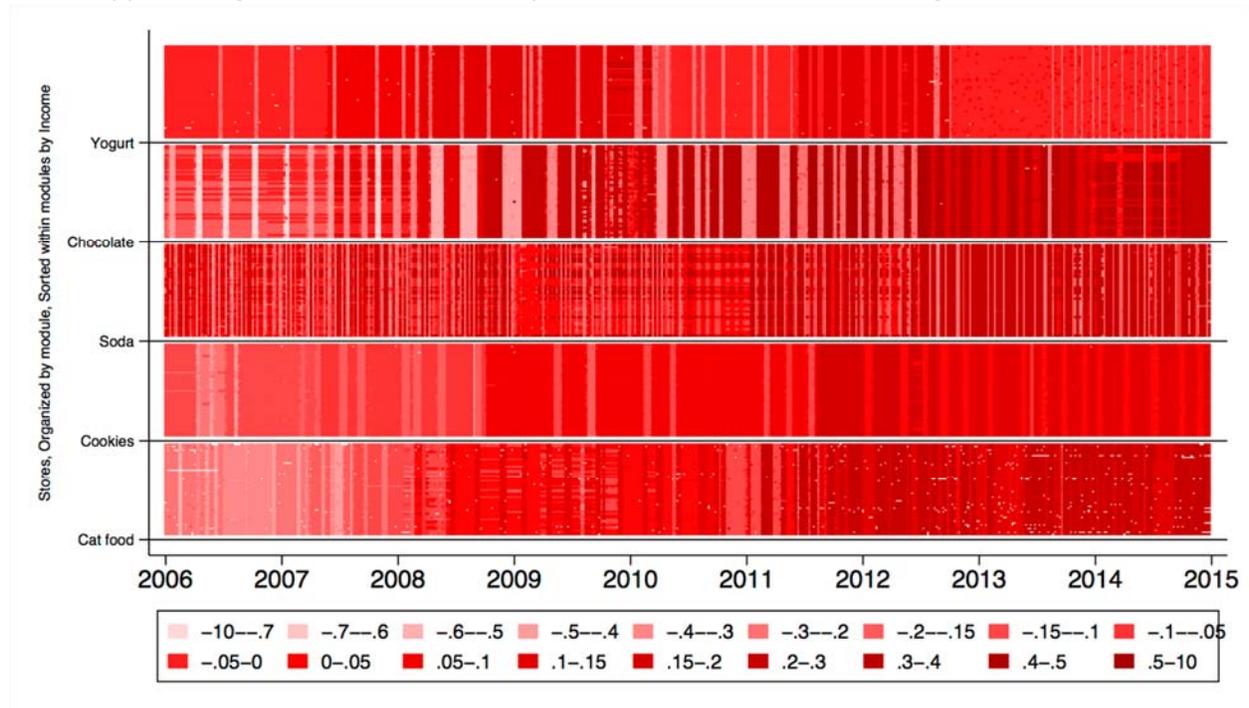

Outcome:	Estimated Percent Increase in Prices for Food Stores for a 10% increase in Marginal Cost		
	Price Measure:	Flexible Pricing	Uniform Pricing
Locality of the Shock	(1)	(2)	(3)
<i>Panel A. Impact on Prices from:</i>			
10% Cost Shock in All Stores	10%	10.22%	10.22%
10% Cost Shock to All Stores in its State	10%	3.39%	3.39%
10% Cost Shock to All Stores in its County	10%	0.23%	0.23%
<i>Panel B. Impact on Prices in California from:</i>			
10% Cost Shock in All Stores	10%	10.24%	10.24%
10% Cost Shock in CA Stores	10%	7.81%	7.81%
10% Cost Shock in Nevada Stores	0%	0.75%	0.75%
<i>Panel C. Impact on Prices in Nevada of:</i>			
10% Cost Shock in All US Stores	10%	10.22%	10.22%
10% Cost Shock in CA Stores	0%	4.27%	4.27%
10% Cost Shock in Nevada Stores	10%	1.88%	1.88%

Notes: Displayed are the estimated percent price response to a permanent 10% shock in the marginal cost in each locality based on three different pricing strategies. In Panel A, the averages are the mean response for stores in each locality, weighting each locality equally. Uniform Pricing assumes that chains set one uniform price across all stores. Actual pricing assumes that chains set their average price to the uniform price but vary the prices in their stores based on $\log(\text{elasticity}/(\text{elasticity}+1))$ residuals using the coefficient in Table 6 Column 1. In all cases, stores use the same pricing strategy both before and after the shock.

Online Appendix Figure 1a. Additional Examples of Chains with Uniform Pricing: Chain 2

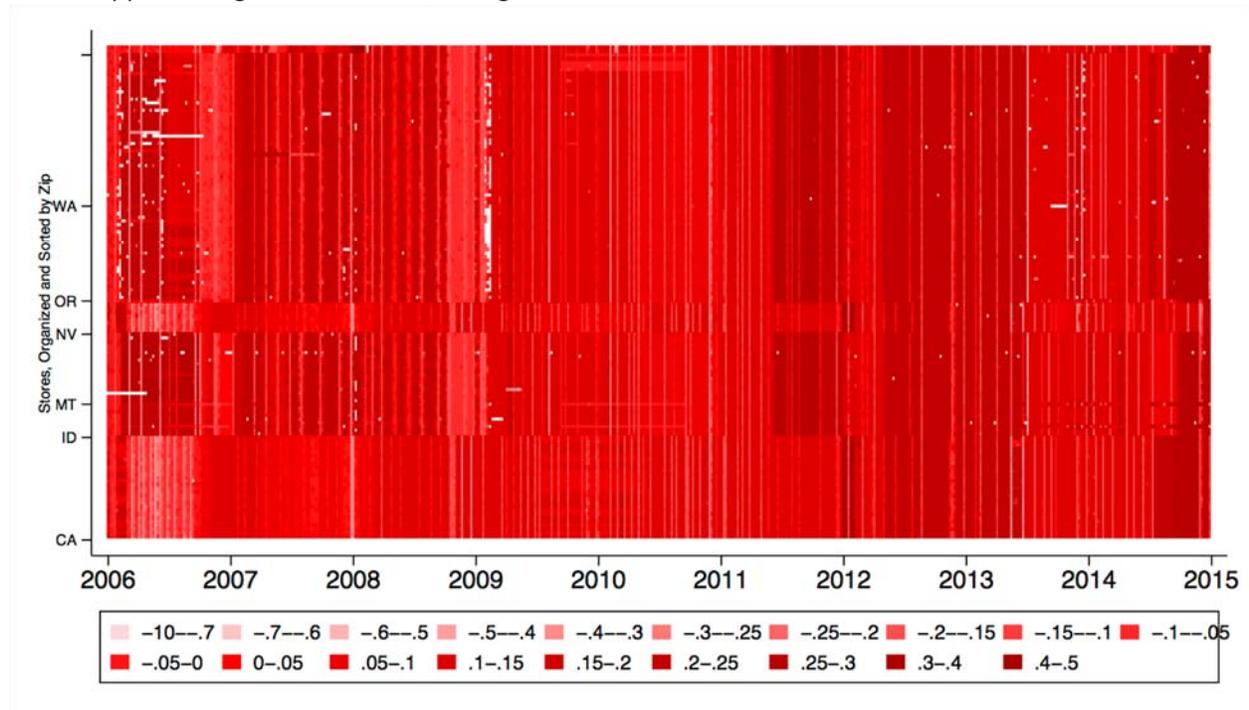

Online Appendix Figure 1b. Additional Examples of Chains with Uniform Pricing: Chain 79

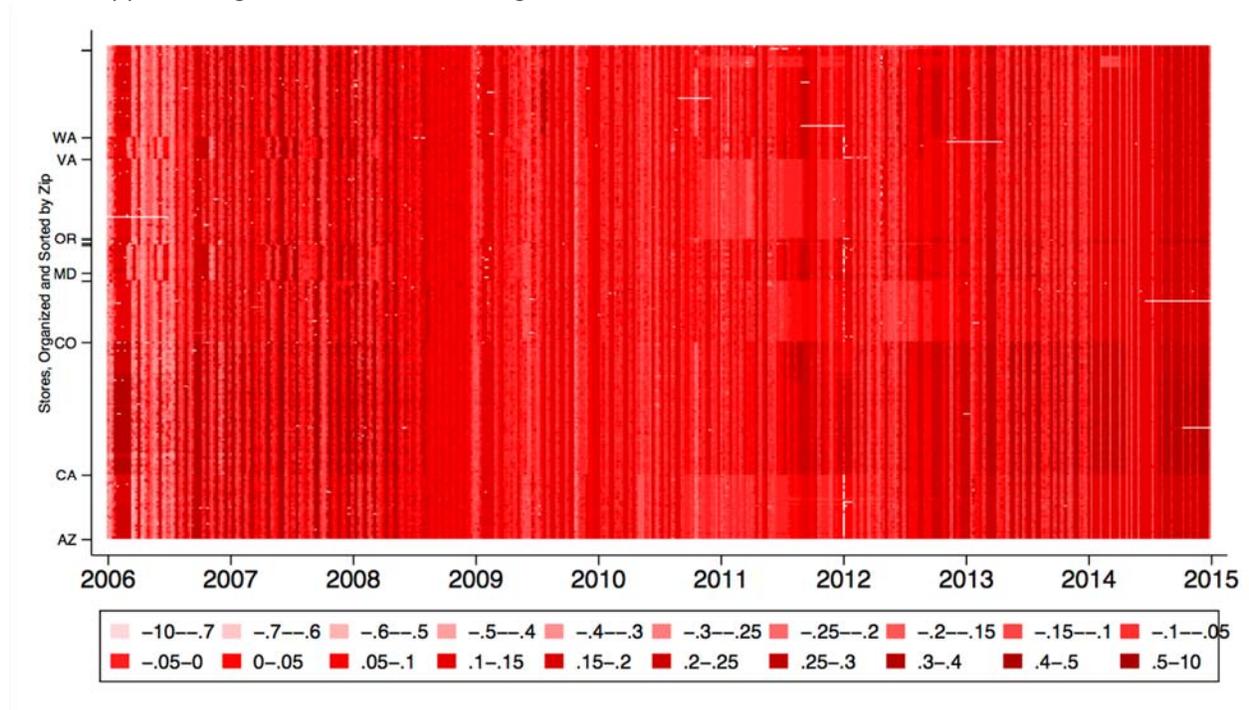

Notes: Plots depict log price in store s and week t for a particular product j . To facilitate comparison across products, we standardize prices by demeaning the log price by the average log price across all stores s in all chains, within a year. Thus, a log price of 0.1 indicates a price that is 0.1 log points higher than on average. Darker colors indicate higher price and are blank if price is missing. Each column is a week. Each row is a store, and stores are sorted by store-level income per capita. In Figure 1a, dividers are \$10,000s differences in the per-capita income measure. In Figure 1b, the same 50 stores appear for each product.

Online Appendix Figure 2. Additional Examples of Chains with Zone Pricing
 Online Appendix Figure 2a. Chain 9, Orange Juice

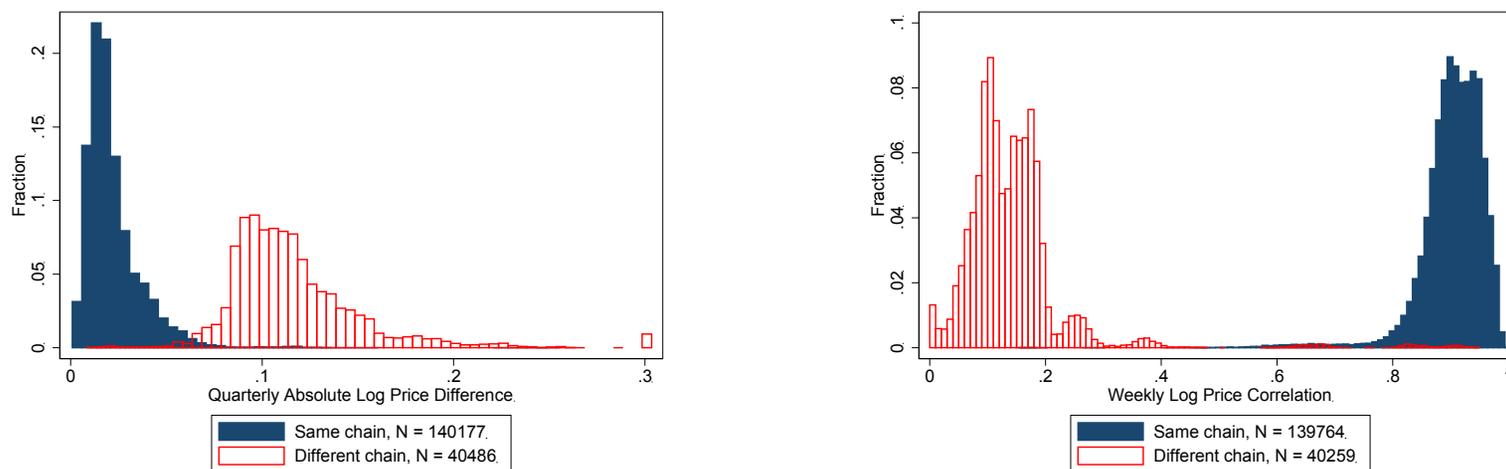

Online Appendix Figure 2b. Chain 32, Orange Juice

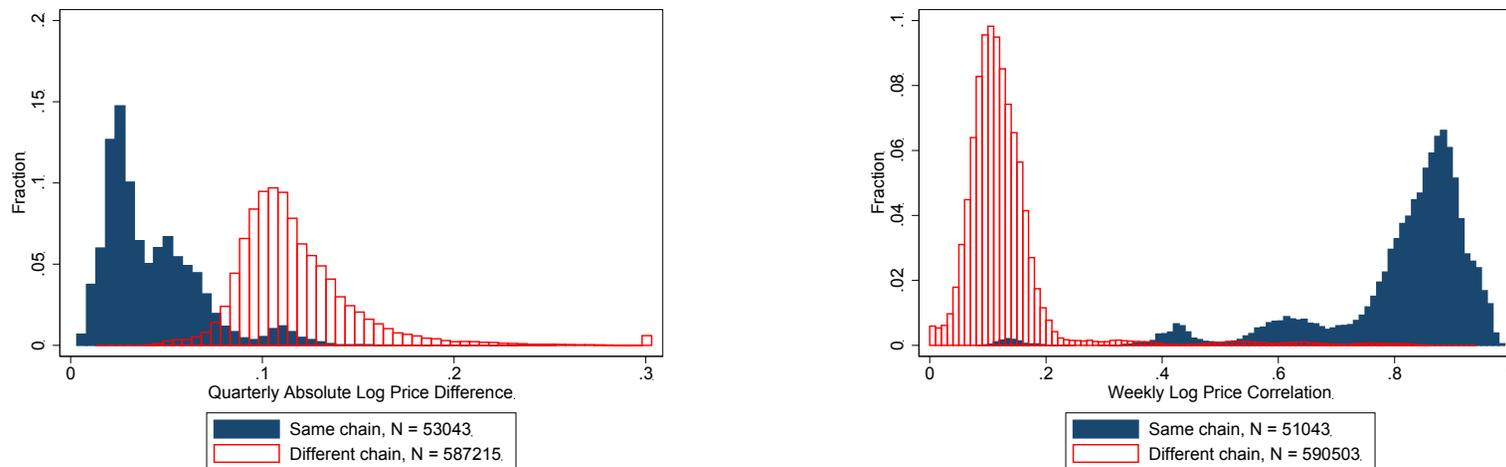

Notes: Plots depict demeaned log prices, same as in Figure 1. The only difference is that stores are not sorted by per-capita income (as in Figure 1) but are instead sorted first by state and then by the three-digit zip code of the store within each state.

Online Appendix Figure 3a-b. Similarity in Pricing across Stores, restricting store pairs to be in the same DMA

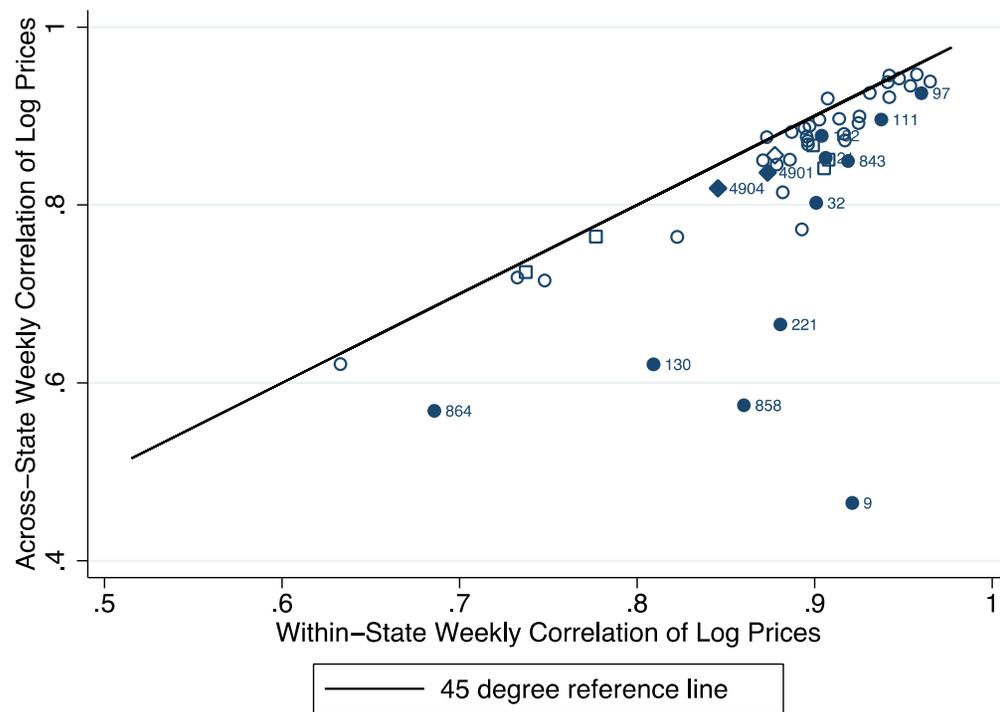

Online Appendix Figure 3c-d. Similarity in Pricing across Stores, for store pairs across DMA and top third vs. bottom third of income only.

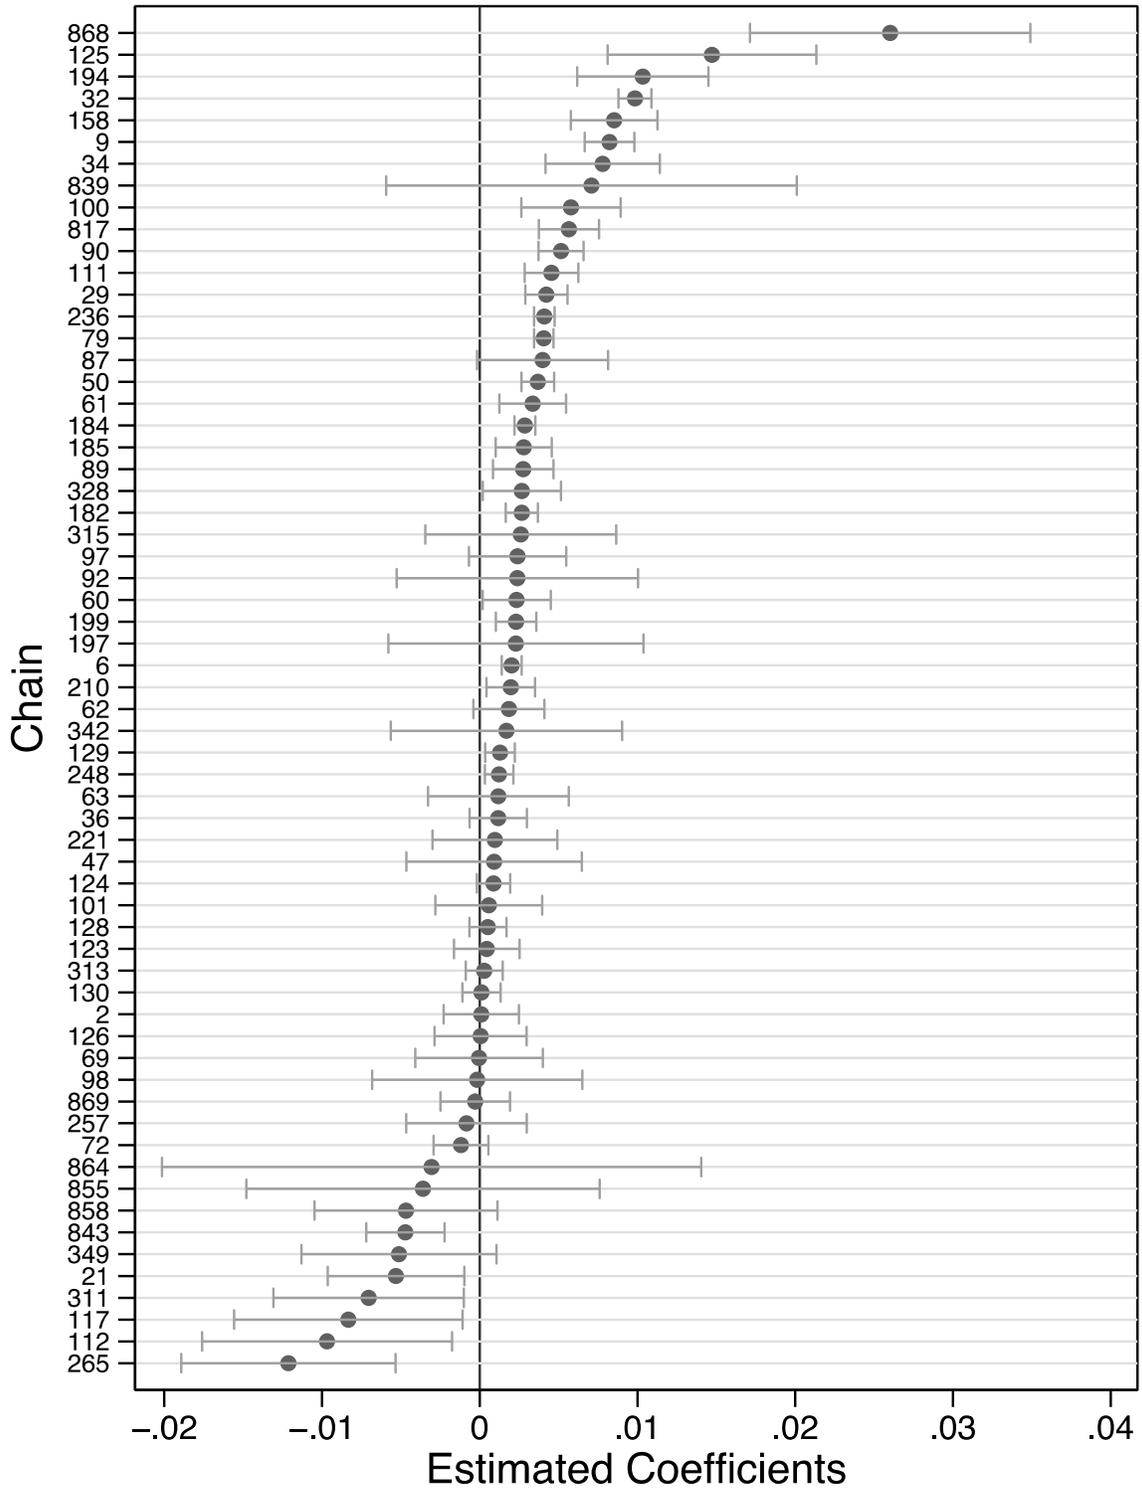

Notes: Each observation in the histograms is a pair of stores. The “same chain” pairs are formed from stores belong to the same chain; the “different chain” pairs are formed from stores in different chains. O. A. Figure 3a-b is restricted to pairs of stores located in the same DMA, while O. A. Figure 3c-d is restricted to pairs of stores located in different DMAs, with the additional restriction that one store in the pair have per-capita income in the bottom third, with the other stores in the pair with per-capita income in the top third. O.A. Figure 3a-c displays the distribution of the average absolute difference in log (quarterly prices) between two stores in a pair, winsorized at 0.3. O. A. Figure 3b-d displays the distribution of the correlation in the weekly (demanded) log prices between two stores, winsorized at 0.

Online Appendix Figure 4. Between and Within-State Weekly Correlation of Log Prices

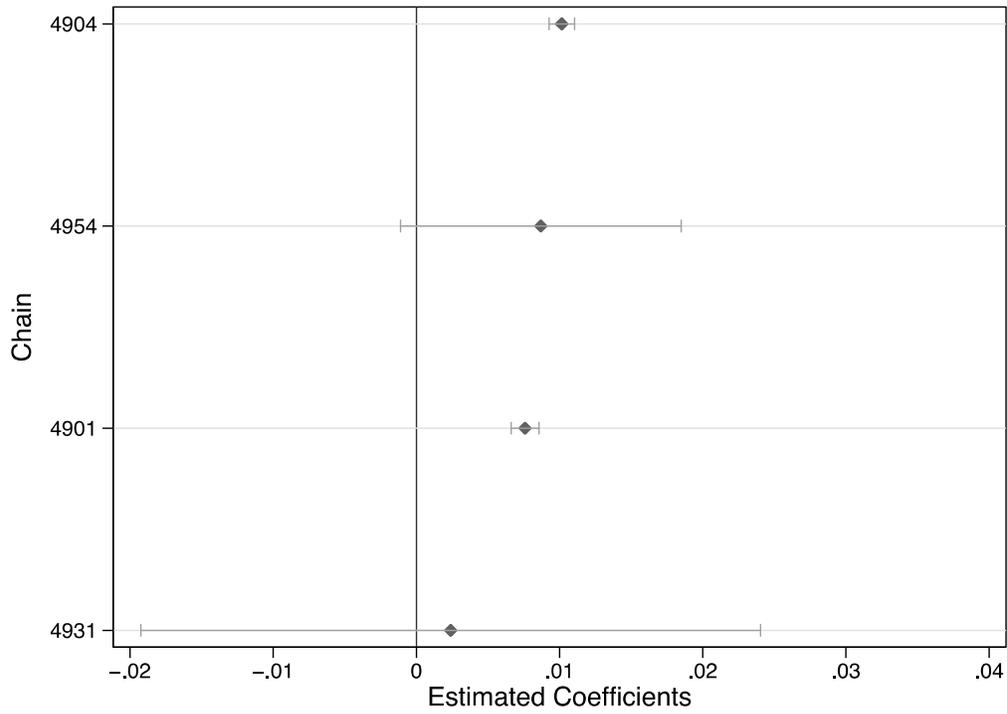

Notes: Each observation is a chain that operates at least three stores in multiple states. Chains that differentiate pricing geographically (identified based in Figure 4b) are labeled. Circles represent food stores, diamonds represent drugstores, and squares represent mass-merchandise stores.

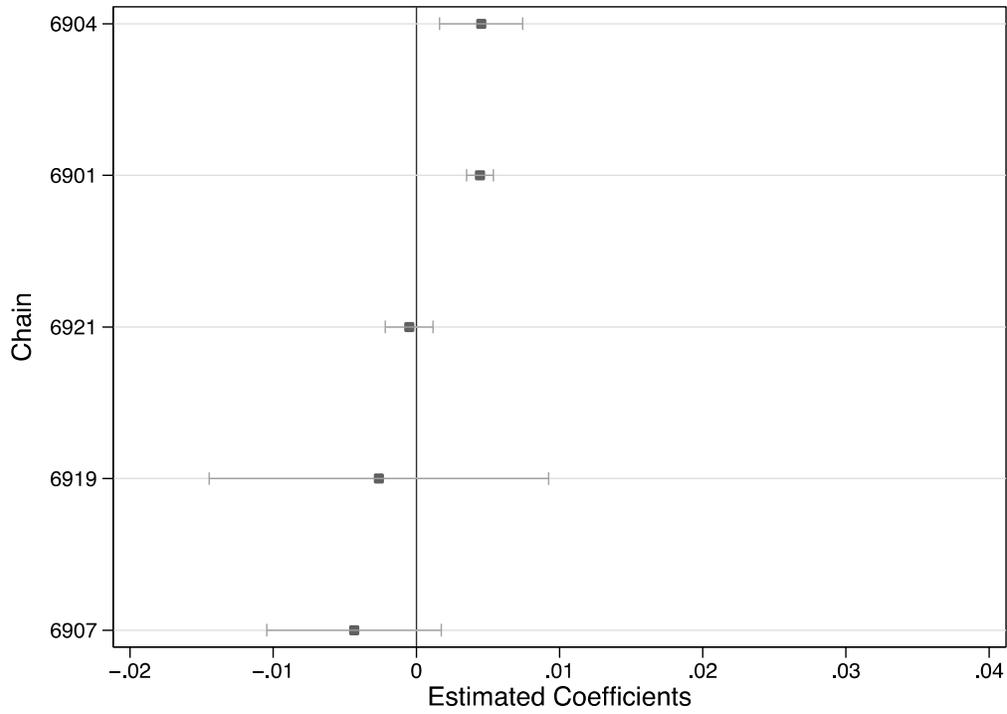

Online Appendix Figure 6. Within-Chain Response of Prices to Income, By Chain
Online Appendix Figure 6a. Food Stores

Online Appendix Figure 6b. Drugstores

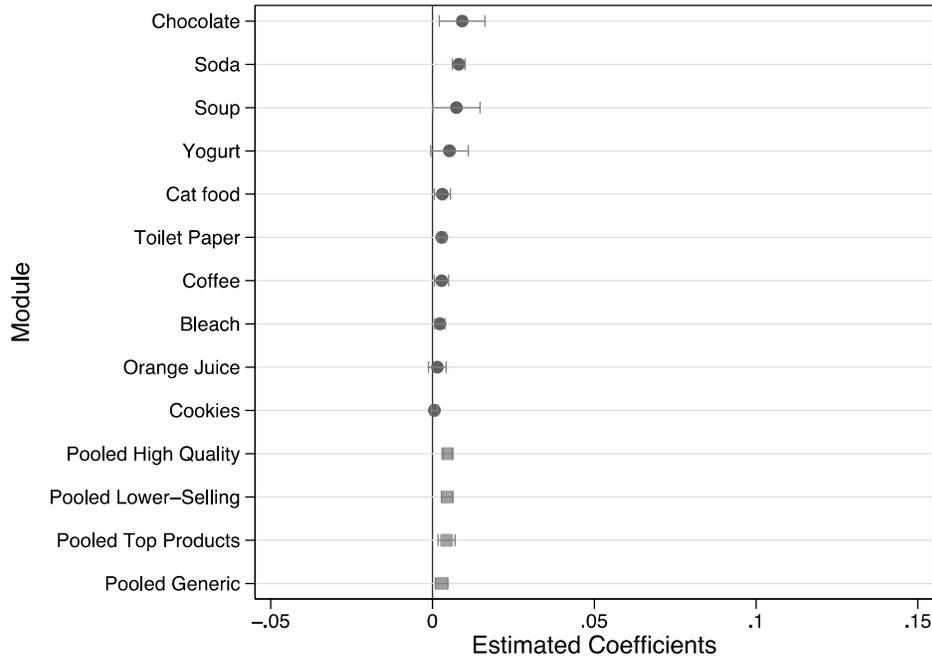

Online Appendix Figure 6c. Mass-Merchandise Stores

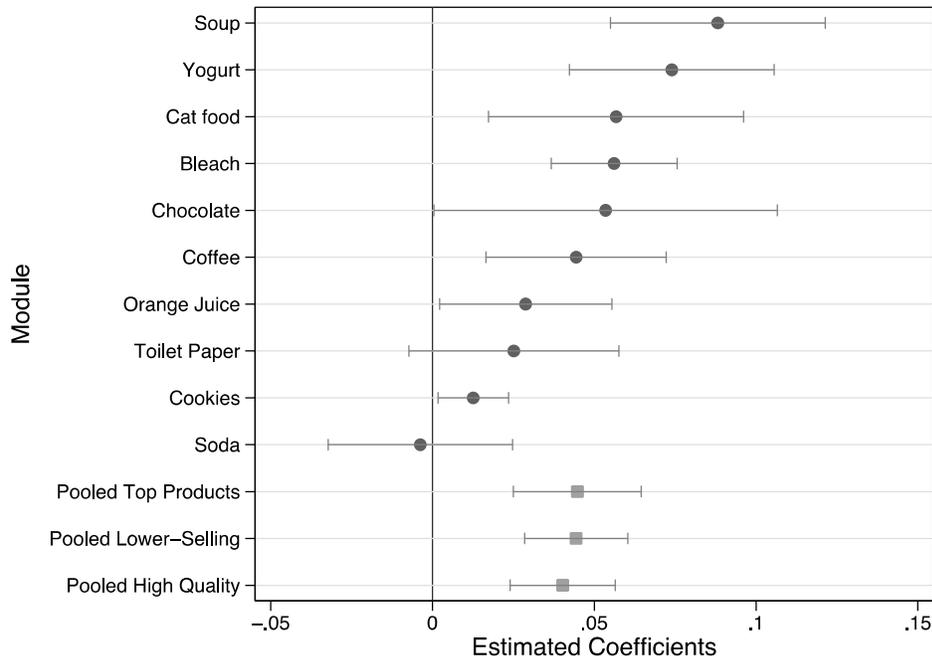

Notes: Plotted are the coefficients of regressions of log price in store-level income run chain-by-chain, with 95% confidence intervals based on robust standard errors. A coefficient of 0.01 means that within chain c , prices are set 1 log point (1%) higher for an increase in income of \$10,000. In Online Appendix Figure 6a, two chains with $SE > .02$ are omitted.

Online Appendix Figure 7. Price vs. Income by module/product group (Food stores only)
 Online Appendix Figure 7a. Within-chain Price vs. Income Regression

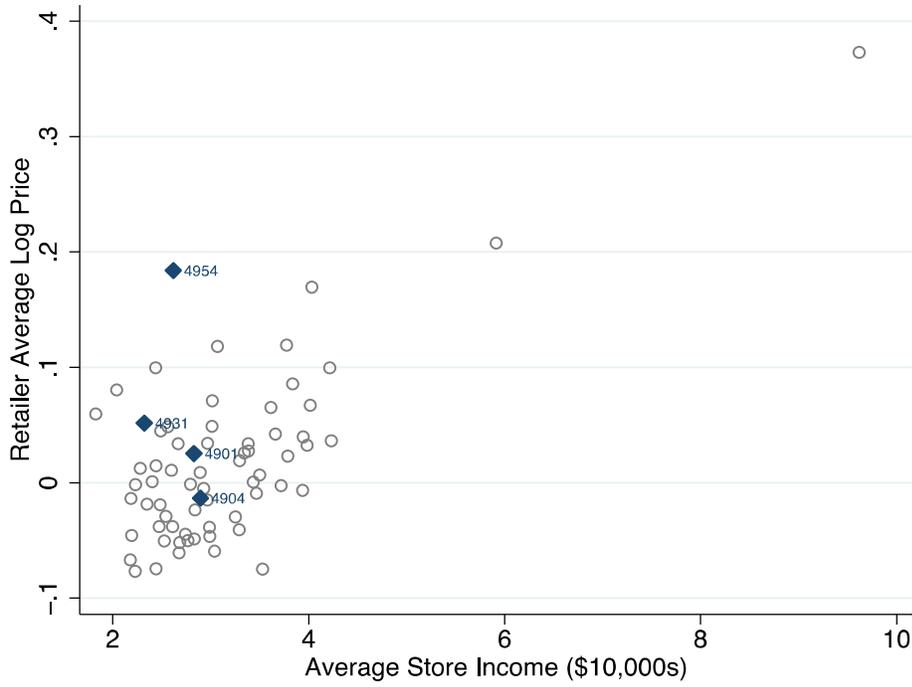

Online Appendix Figure 7b. Between-Chain Price vs. Income Regression (Food Stores Only)

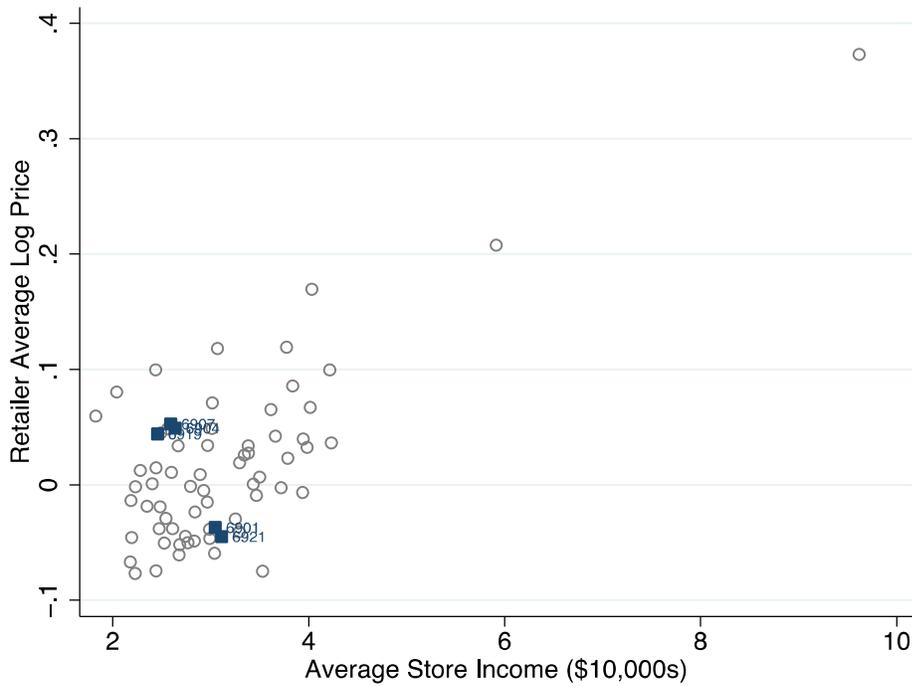

Notes: Onl. App. Figure 7a plots the coefficients of regressions of log price on store-level income with chain fixed effects, where the regression is run separately for each group of products, with 95% confidence intervals based on robust standard errors. A coefficient of 0.01 means that within chain c , prices are set 1 log point (1%) higher for an increase in income of \$10,000. Figure 7b plots the same relationship for the chain-level regression of average chain-level price on average chain-level income but for chain averages using analytic weights equal to number of stores with standard errors again clustered by parent_code. Squares indicate pooled price averaging over multiple products, while circles indicate individual products.

Online Appendix Figure 8. Between-Chain Relationship of Price to Income, Drug and Mass Merchandise Chains

Online Appendix Figure 8a. Drugstore Chains

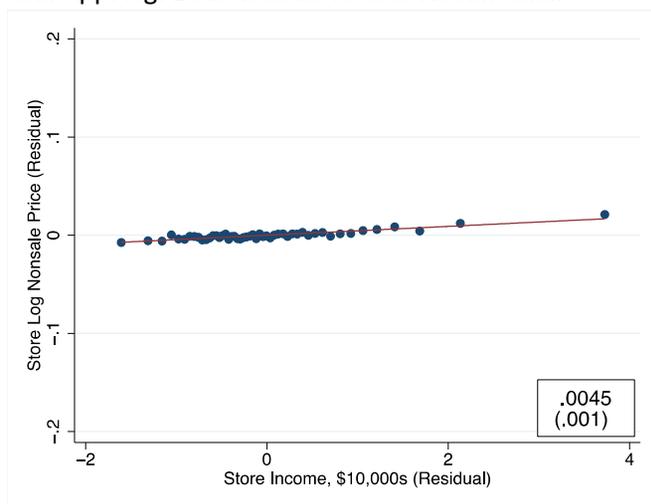

Online Appendix Figure 8b. Mass-Merchandise Chains

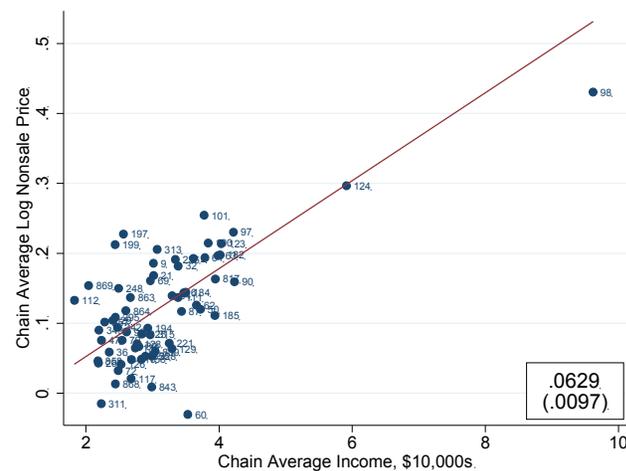

Notes: Plotted are scatterplots of average price on average income at the chain level, with the labels indicating a chain identifier. Hollow circles representing food store chains are for reference.

Onl. App. Fig. 10c. Nonsale Prices: Within-Chain-State

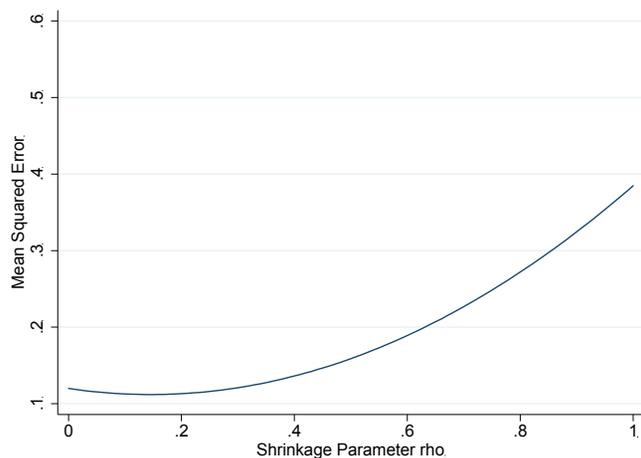

Onl. App. Fig. 10d. Nonsale Prices: Between-Zones Relationship

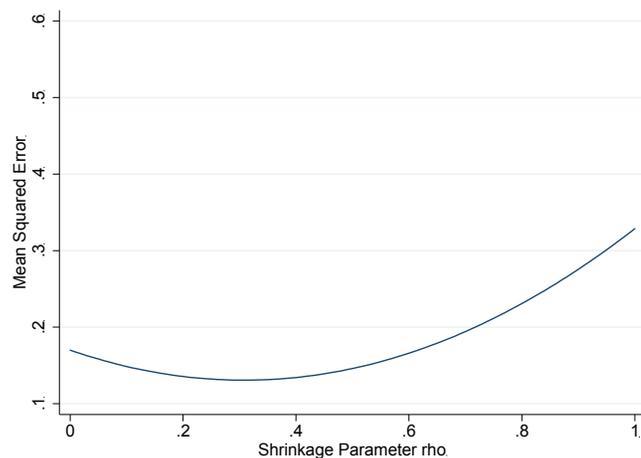

Notes: Online Appendix Figure 10 presents the same evidence as Figure 5, except that it uses as price variable a measure of non-sale price which we build in the Nielsen RMS data. We keep only prices that are above the 80th percentile of prices in a given store-year-module. Further, we require that a given price is charged for 3 weeks in a row (two weeks in a row for the first and last weeks of each year). Additional details are in Appendix A.1.8.

Online Appendix Figure 11. Shrinkage of Store-Level Elasticity

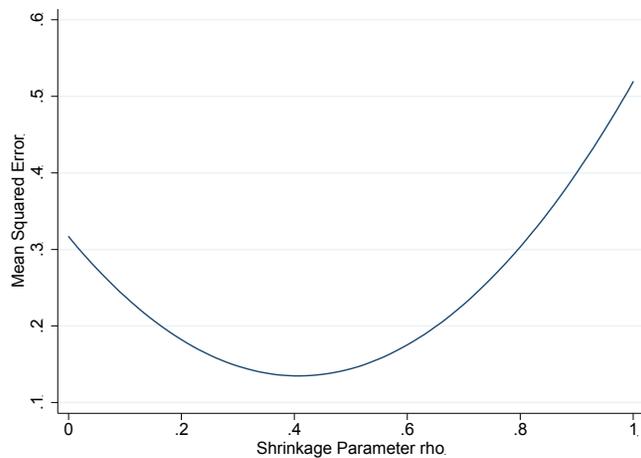

Online Appendix Figure 11a. Food Stores

Online Appendix Figure 11b. Drugstores

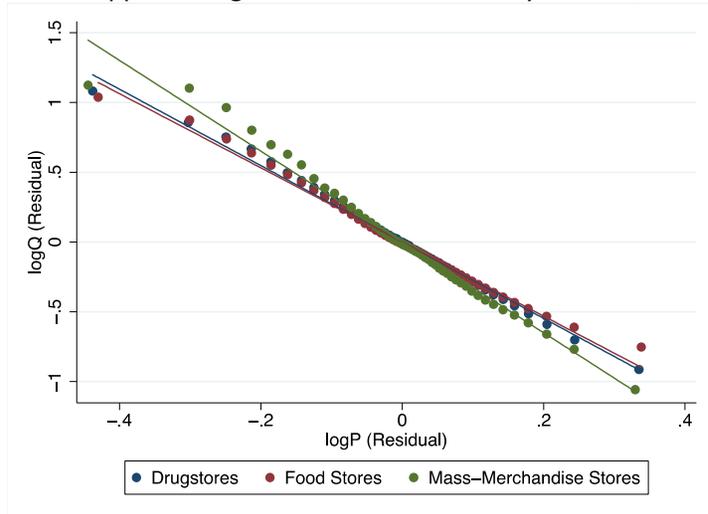

Online Appendix Figure 11c. Mass-Merchandise Stores

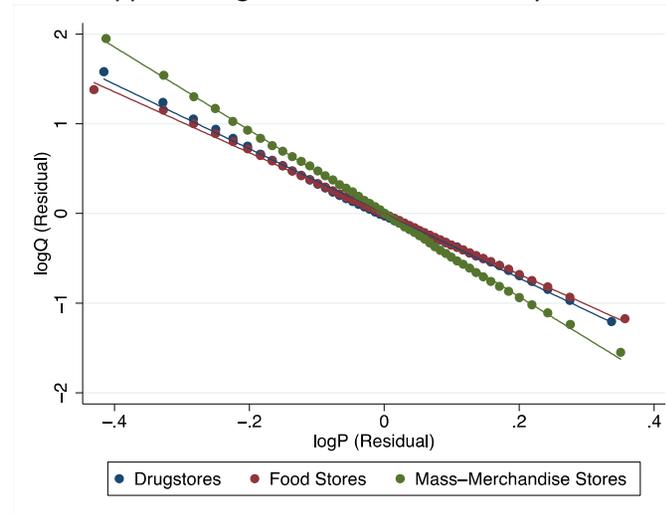

Notes: Plotted is the mean squared error for various choices of shrinkage parameter ρ for the store-level elasticity estimates. For the purpose of computing the optimal shrinkage, we compute store-level elasticities using only prices and quantities from the first half of each year. The shrunk elasticity is a weighted average with weight $1-\rho$ on this estimate and weight ρ on the mean elasticity. We then compute the mean squared error between this shrunk elasticity and the elasticity estimated in the second half of the year. The plots display the mean squared error as a function of various values of ρ . The optimal shrinkage parameter is $\rho=0.104$ for food store (Figure 11a), $\rho=0.305$ for drug stores (Figure 11b) and $\rho=0.408$ for mass merchandise stores (Figure 11c).

Online App. Figure 12c. Food Store Incremental R-squared

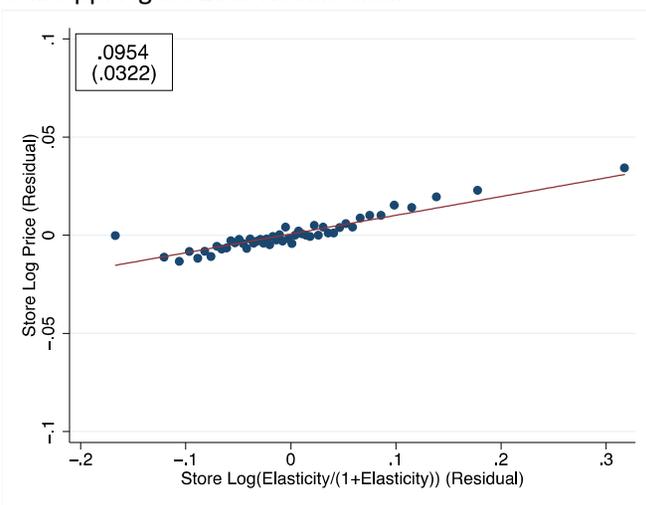

Online App. Figure 12d. Food Store Stockpiling Evidence: Lags and Leads

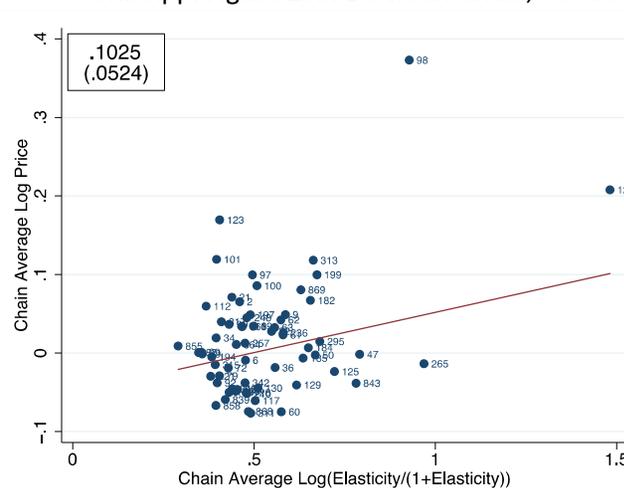

Notes: O. A. Figure 12a plots a bin scatter with 50 bins representing 60,552,601 store-module-weeks of log Q on log P, after taking out module*week-of-year and module*year FE. Figure 12b shows the same but for the soda product only (9,865,925 store-weeks). Figure 12c shows the distribution of R-squared using the pooled regression of all 10 products in food stores only. In Figure 12d., module-level regressions are estimated using all food stores together with store, year, and week-of-year fixed effects, unlike our main specification (which consists a separate regression for each store).

Onl. App. Figure 13b. Between-Chain, Food stores only

Onl. App. Figure 13c. Within-Chain-State

Onl. App. Figure 13d. Between-State, Within-Chain

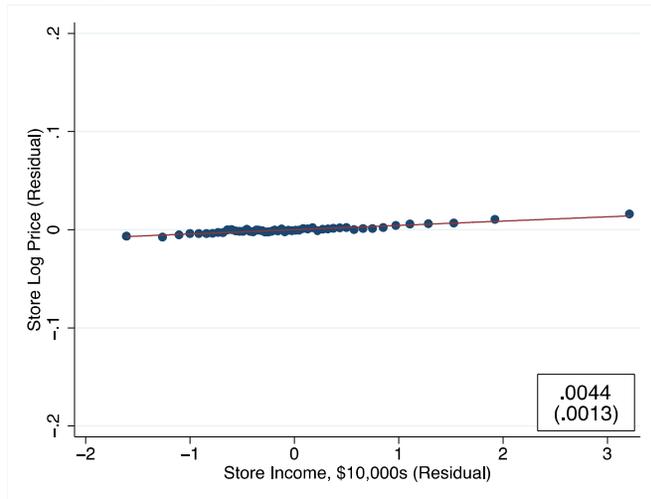

Notes: Onl. App. Figure 13a,c plot bin scatters with 50 bins of the residual of log price on the residual of $\log(\text{elasticity}/(1+\text{elasticity}))$ in store s . Residuals are after removing Chain FE (Figure 13a) and ChainXState FE (Figure 13c). Figure 13b plots a scatter of average price on the average log elasticity term at the chain level for the food stores, with the labels indicating a chain identifier. Figure 13d plots a bin scatter with 25 bins of chain-state averages of log price and the log elasticity term. The figures report the coefficient of the relevant regressions, with standard errors clustered by parent_code. Axes ranges have been chosen to make the slopes visually comparable. Analytic weights equal to the number of stores in each unit are used for the regression in Figures 13b and 13d.

Online Appendix Figure 15b. Correlation with Benchmark Elasticity

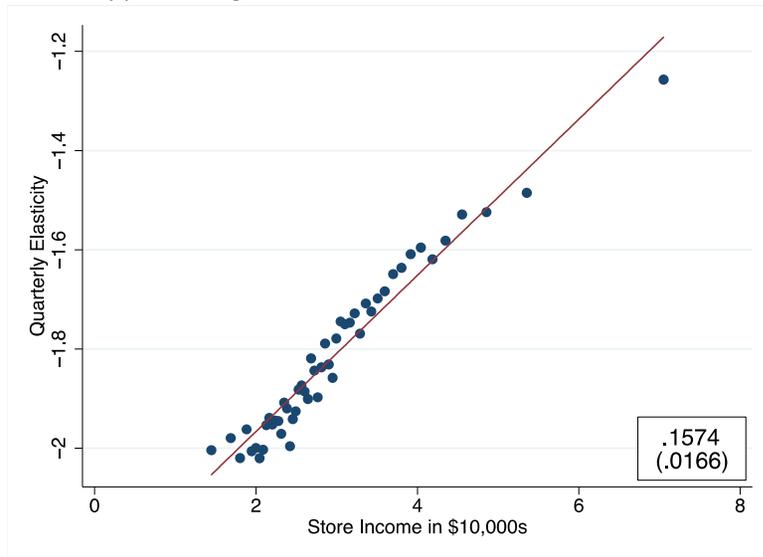

Online Appendix Figure 15c. Test of Linearity

Online Appendix Figure 15d. Distribution of Standard Errors

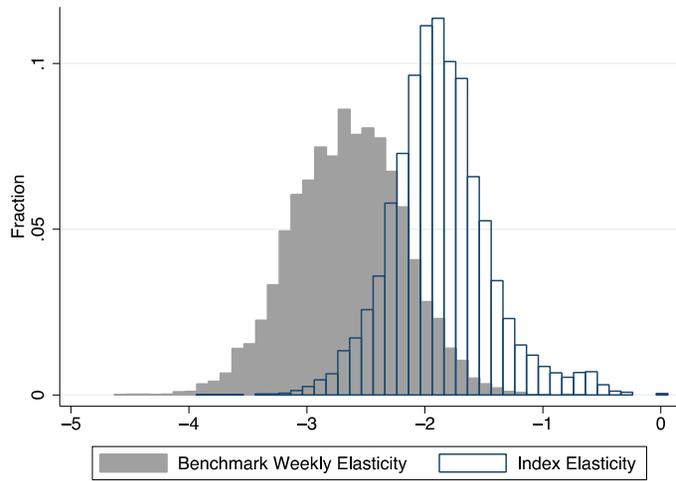

Online Appendix Figure 15e. Correlation with Income

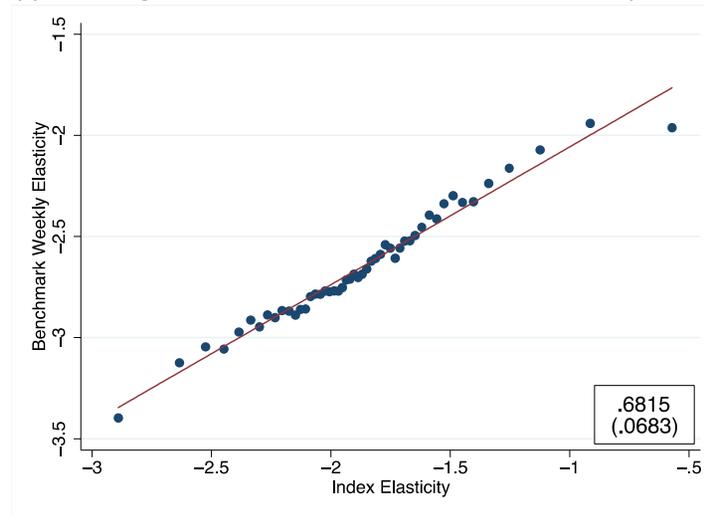

Notes: Online Appendix Figure 15a plots the distribution of the estimated quarterly elasticity for the food stores from a regression at the quarterly level of log Q on log P with controls for quarter-of-year and year; the figure compares the distribution of this quarterly elasticity with the distribution of the benchmark elasticity computed at the weekly level. Estimated elasticities are Winsorized at 0 and -5. Online Appendix Figure 15b plots the bin scatter of our benchmark weekly store elasticity against the quarterly elasticity using 50 bins representing 9,415 stores. Standard errors are clustered by parent_code. Online Appendix Figure 15c, plots a bin scatter with 50 bins representing 3,488,542 store-module quarters of log Q on log P, after taking out module*quarter-of-year and module*year FE. Online Appendix Figure 15d plots the distribution of the standard errors, Winsorized at 0.8. Online Appendix Figure 15e plots a bin scatter with 50 bins of representing 9,415 stores of the elasticity on the store-level income, after residualizing the Chain FE. Standard errors are clustered by parent_code.

Online Appendix Figure 16. Weekly Price Index Elasticity Estimates and Validation (Food Stores Only)

Online Appendix Figure 16b. Relation to Benchmark elasticity

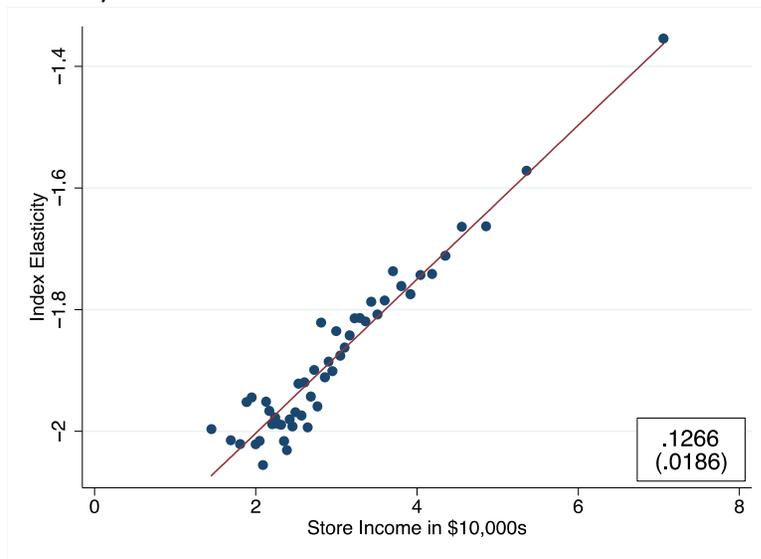

Online Appendix Figure 16c. Test of Linearity

Online Appendix Figure 16d. Distribution of Standard Errors

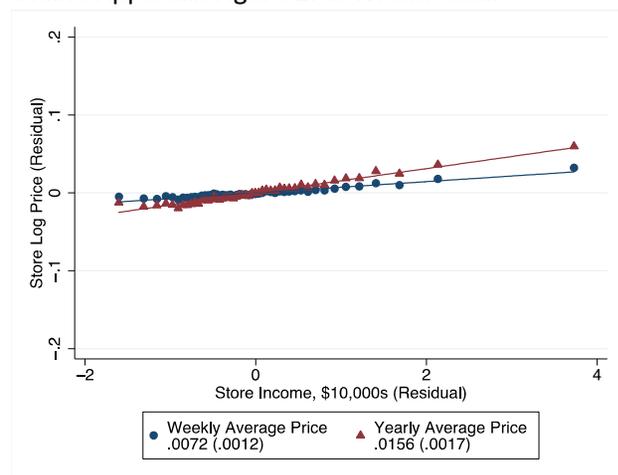

Online Appendix Figure 16e. Index Elasticity
Elasticity vs. Income

Notes: Online Appendix Figure 16a plots the distribution of the estimated elasticity for the food stores computed using an index of products, as opposed to using just a benchmark product, as in our benchmark elasticity measure. The index elasticity is computed from a regression at the weekly level of $\log Q$ on $\log P$, where $\log Q$ and $\log P$ are aggregated from an index of products within a module, with weights given by the yearly quantity sold at the module-year level. Estimated elasticities are Winsorized at 0. Online Appendix Figure 16b plots the bin scatter of our benchmark weekly store elasticity against the index elasticity using 50 bins representing 9,415 stores. Standard errors are clustered by parent_code. Online Appendix Figure 16c plots a bin scatter with 50 bins representing 39,778,208 store-module weeks of $\log Q$ on $\log P$, after taking out module*week-of-year and module*year FE. Online Appendix Figure 16d plots the distribution of the standard errors, Winsorized at 0.4. Online Appendix Figure 16e plots a bin scatter with 50 bins of representing 9,415 stores of the index elasticity on the store-level income, after residualizing the Chain FE. Standard errors are clustered by parent_code.

Online Appendix Figure 17. Weekly Average Price versus Yearly Average Price

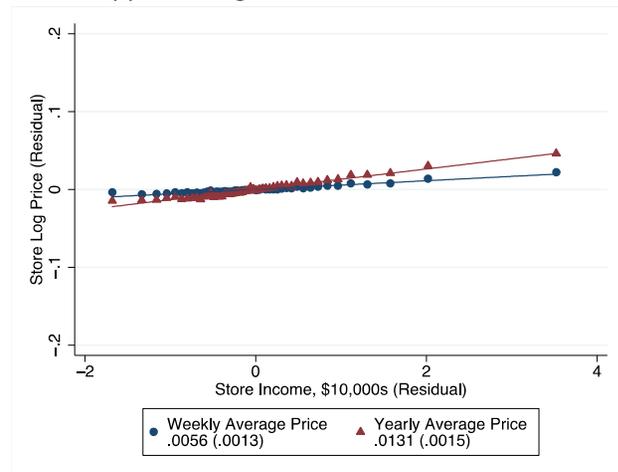

Online Appendix Figure 17a. Within-Chain

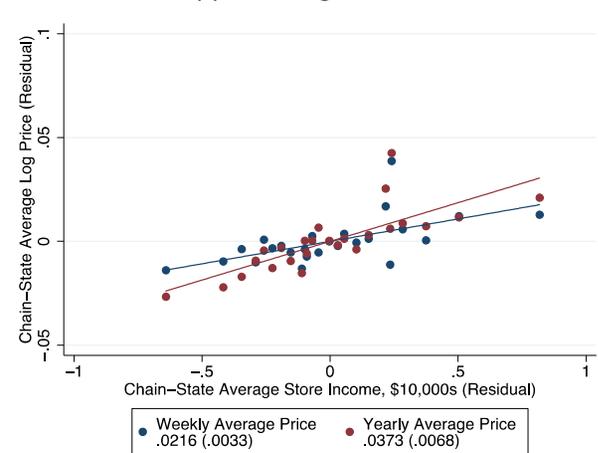

Online Appendix Figure 17b. Between-Chain (Food Stores only)

Online Appendix Figure 17c. Within-Chain-State

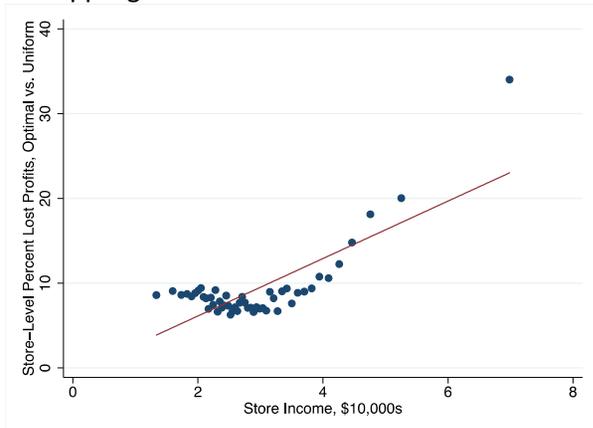

Online Appendix Figure 17d. Between Chain-State

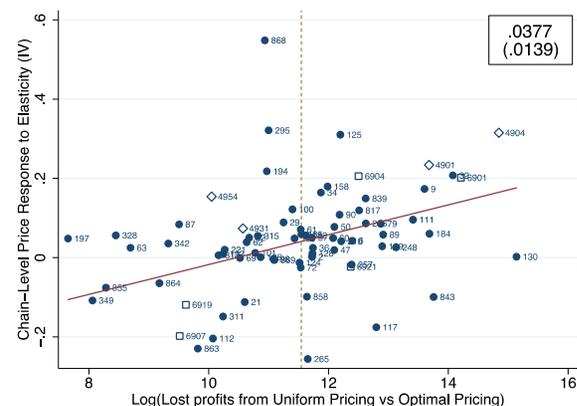

Notes: In Onl. App. Figures 17a-d we compare the price-income relationship for our benchmark measure of weekly average price to a measure of yearly average price, computed as the ratio of yearly revenue to yearly units sold. Online Appendix Figure 17a,c plot bin scatters with 50 bins of the residual of log price in store s on the residual of income in store s . Residuals are after removing Chain FE (Figure 17a) and ChainXState FE (Figure 17c). Online Appendix Figure 17b plots a scatter of average price on average income at the chain level, with the labels indicating a chain identifier. Onl. App. Figure 17d plots a bin scatter with 25 bins of chain-state averages of both log price and income. The figures report the coefficient of the relevant regressions, with standard errors clustered by parent_code. Axes ranges have been chosen to make the slopes visually comparable. Analytic weights equal to the number of stores in each aggregation unit are used for the regression in Onl. App. Figures 17b,d.

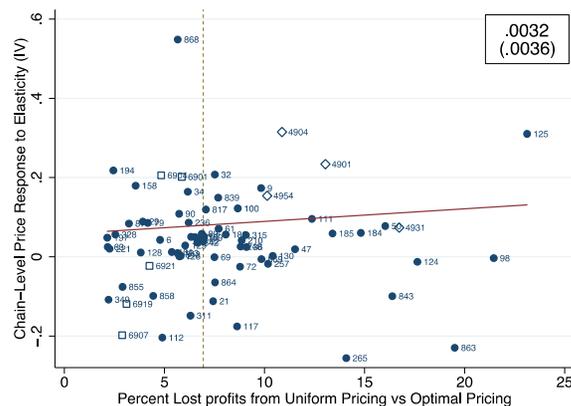

Online Appendix Figure 18. Profit Loss from Uniform Pricing
 Onl App Figure 18a. Store-Level Lost Profits vs. Income

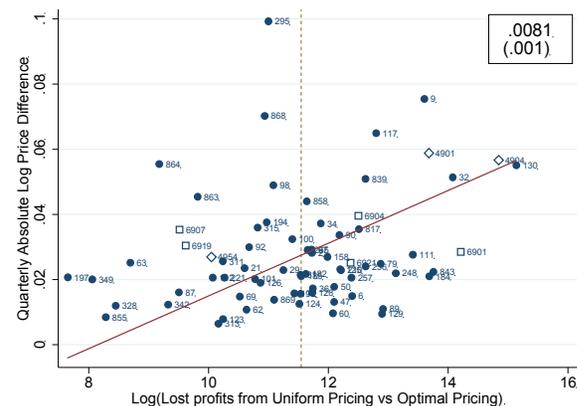

Onl App Figure 18b. Chain Price-Elasticity Slope (IV) vs Log(Profits Lost)

Onl App Figure 18c. Chain Price-Elasticity Slope (IV) vs. % Profit Loss

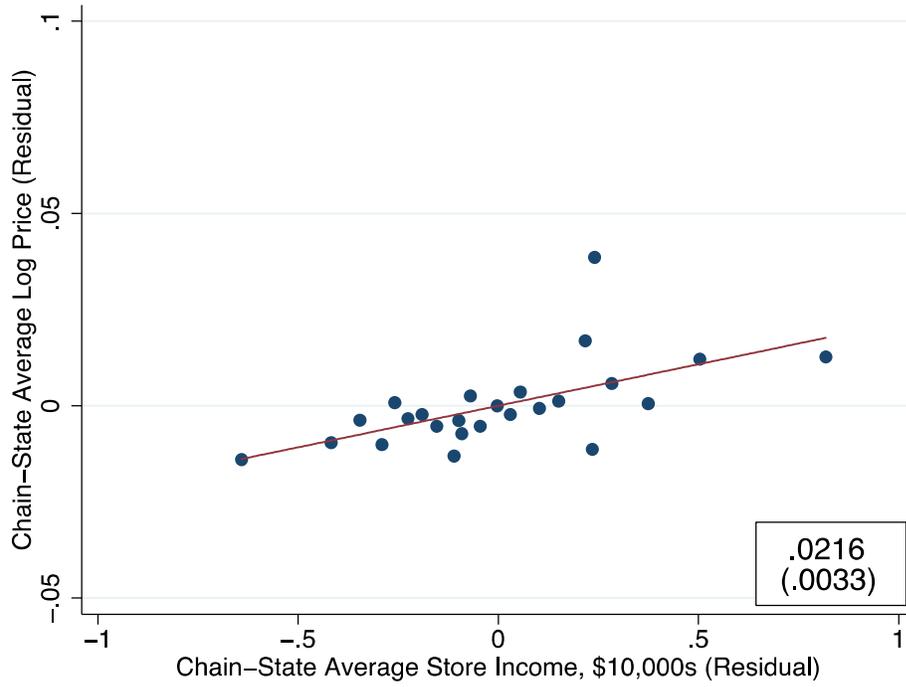

Onl App Figure 18d. Avg Quarterly Absolute Log Diff. vs Log(Profits Lost)

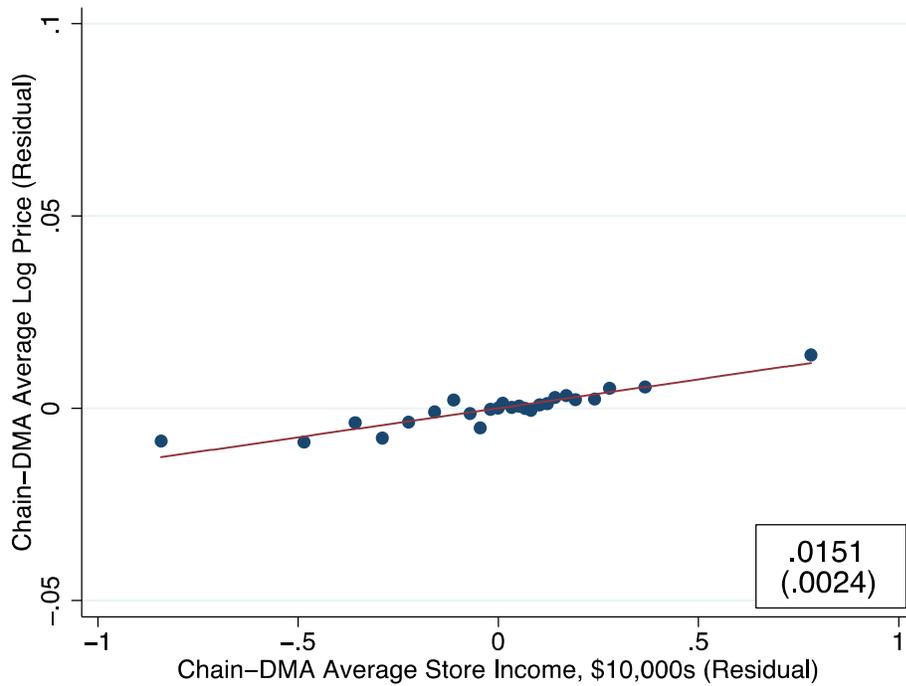

Notes: O. A. Figure 18a relates store-level profit losses to store-level income. Figures 18b-d relate a chain-level measure of fully flexible pricing to a chain-level measure of profit losses due to uniform pricing. Marginal Cost is estimated and is defined to be constant within each chain-product throughout. In Figure 18bd, the measure is the log of the sum of estimated profits from optimal flexible pricing (according to our monopolistic competition model) less estimated profits for uniform pricing, scaled up to the average yearly revenue of each store. In Figure 18c, the measure of profit losses is the estimated loss from fully uniform pricing, compared to the profits from optimal pricing as a percent of the profits under optimal pricing. As measure of flexible pricing in Figures 18bc, we use the chain-level coefficient of price on log elasticity (instrumented with income). These are the reduced form coefficients in Online Appendix Figure 6 divided by the first stage coefficient in Table 5 columns 6-8. Dashed vertical line indicates median values for the measures of profit loss. Figure 18bc use analytic weights equal to the inverse SE squared of the reduced form chain-level coefficient of price on income. Chain 295 (simulated 68% lost profits) has been omitted from Figure 18c. Figure 18d uses chain average quarterly absolute log price difference as the measure of flexible pricing and uses analytic weights equal to the number of stores in the chain.

Online Appendix Figure 19. Test for Advertising Constraints
 Online Appendix Figure 19a. Chain-State Zones

Online Appendix Figure 19b. Chain-DMA Zones

Notes: Online Appendix Figure 19a plots a bin scatter with 25 bins of chain-state averages of both log price and income after removing chain fixed effects. Online Appendix Figure 19b plots a bin scatter with 25 bins of chain-DMA averages of both log price and income after removing chainXstate fixed effects. The figures report the coefficient of the relevant regressions, with standard errors clustered by parent_code. Analytic weights equal to the number of stores in each chain-region are used.

Online Appendix Table 1. Additional Summary Statistics

	No. of Stores	No. of Chains	No. of States
	(1)	(2)	(3)
<i>Panel A. Main Sample by Year</i>			
2006	19,252	64	48+DC

2011	21,666	73	48+DC
2012	21,669	73	48+DC
2013	21,331	73	48+DC
2014	20,666	70	48+DC
	Yearly Module Revenue by Store (in \$)	% of Module Revenue Captured	Average Price
	(1)	(2)	(3)
<i>Panel B. Index Characteristics, Food Stores</i>			
Canned Soup	\$55,500	34.0%	\$1.15
Cat Food	\$11,000	19.8%	\$0.49
Chocolate	\$41,500	21.3%	\$0.87
Coffee	\$30,000	15.5%	\$5.80
Cookies	\$50,500	24.5%	\$2.33
Soda	\$240,500	53.1%	\$1.98
Orange Juice	\$77,500	62.2%	\$3.09
Yogurt	\$80,500	41.6%	\$0.82
Bleach	\$7,500	41.2%	\$1.84
Toilet Paper	\$75,500	32.2%	\$4.42

Notes: Panel A reports the number of stores and chains in our main sample for each year. In Panel B, we present summary statistics on the price index computed aggregating within each module all products (UPCs) available in at least 95% of week-store observations for that chain (details in the text). We report the average yearly revenue at the store level for all the products included in the index (Column 1), the percent of module revenue covered by the basket (Column 2) and the average price of the products included in our index (Column 3).

Online Appendix Table 2. Price versus Income, Within Chain and Between Chain

R Squared	0.652	0.629	0.601	0.659	0.660	0.700	0.398	0.589
Number of Observations	22,660	22,660	22,660	22,660	22,660	9,415	9,410	9,262

Notes: Standard errors are clustered by parent_code. Elasticities are Winsorized to -1.2 in Columns (6)-(8). All independent variables are our estimate of store-level demographics at the zip-code level based on Nielsen Homescan (HMS) panelists' residences. Demographics are from 2012 ACS 5-year estimates. Fraction with College Degree (or higher) is the fraction of adults 25 and older with at least a bachelor's degree. Controls for Urban Share are a set of dummy variables for Percent Urban for values in [.8, .9), [.9, .95), [.95, .975), [.975, .99), [.99, .999), and [.999, 1]. Columns (7) and (8) do not have the full sample of 9,415 food stores because we excluded stores that had elasticity estimates with large standard errors.

Online Appendix Table 5. Log Prices and Store-Level Log Elasticity, OLS

	Chain 4901	Chain 4904	Chain 4931	Chain 4954	
<i>Panel B. Drugstores</i>					
Loss of Profits Comparing Optimal Pricing to Uniform Pricing	13.05%	10.87%	16.73%	10.13%	
Loss of Profits Comparing Optimal Pricing to Actual Price-Elasticity Slope	6.62%	5.48%	8.63%	5.00%	
Loss of Profits Comparing Optimal Pricing to State-Zone Optimal Pricing	9.51%	8.16%	16.76%	9.86%	
Loss of Profits Comparing Optimal Pricing to Actual Pricing (Raw Prices)	14.24%	10.93%	21.66%	9.46%	
	Chain 6901	Chain 6904	Chain 6907	Chain 6919	Chain 6921
<i>Panel C. Mass Merchandise Stores</i>					
Loss of Profits Comparing Optimal Pricing to Uniform Pricing	5.86%	4.83%	2.89%	3.10%	4.25%
Loss of Profits Comparing Optimal Pricing to Actual Price-Elasticity Slope	3.87%	3.18%	1.91%	2.03%	2.79%
Loss of Profits Comparing Optimal Pricing to State-Zone Optimal Pricing	4.13%	3.78%	1.92%	0.73%	1.69%
Loss of Profits Comparing Optimal Pricing to Actual Pricing (Raw Prices)	10.81%	9.86%	4.64%	12.96%	9.53%

Notes: Elasticities are Winsorized at -1.2. Raw prices are unadjusted observed prices. Chain-State Mean Prices use chain-state means in place of observed prices for every store within a chain-state, effectively enforcing chain-state zone pricing.

Online Appendix Table 8. Determinants of Flexible Pricing II

Dependent Variable:	Mean Quarterly Absolute Log Price Difference for Chain c				
	(1)	(2)	(3)	(4)	(5)
Log (No. of Stores)	0.0050*	0.0017			-0.0083
	(0.0027)	(0.0035)			(0.0091)
Log (No. of States)	-0.0035	-0.0029			-0.0083
	(0.0042)	(0.0042)			(0.0083)
Log (Average Yearly Store Sales)	0.0011	0.0039			0.0078*
	(0.0042)	(0.0047)			(0.0046)
Standard Deviation of Store-level Per-capita Income		0.0204**			0.0114
		(0.0090)			(0.0117)
Log Dollar Profit Loss from Uniform Pricing			0.0061***		0.0066
			(0.0014)		(0.0082)
Percent Profit Loss from Uniform Pricing			0.0016*		0.0004
			(0.0008)		(0.0009)
Share of Stores with Competitor Stores within 10 km				-0.0230	-0.0043
				(0.0145)	(0.0109)
Share of Store with Same-Chain Stores within 10 km				0.0193*	0.0107
				(0.0102)	(0.0131)
Analytic Weights	Y	Y	Y	Y	Y
Number of observations	72	72	72	72	72
R-squared	0.503	0.555	0.486	0.138	0.623

Notes: Standard errors are clustered by parent_code. Analytic weights equal to the number of stores in each chain are used.

Online Appendix Table 9. Evidence for Explanations

Dependent Variable:	Log Prices in Store s			
	Food Chains, <= 200 stores	Food Chains, > 200 stores	Drugstore Chains	Mass-Merchandise Chains
	(1)	(2)	(3)	(4)
<i>Panel A. Within-Chain Tacit Collusion and Fairness</i>				
Log (Elast. / (Elast.+1)) in Store s	0.0611*** (0.0121)	0.102*** (0.0257)	0.253*** (0.0545)	0.117* (0.0651)
Log (Elast. / (Elast.+1)) in Store s * (Zero competitors stores within 10 km) (<i>Tacit Collusion</i>)	0.0000 (0.0275)	0.0070 (0.0344)	-0.0458 (0.0548)	0.160*** (0.0543)
Log (Elast. / (Elast.+1)) in Store s * (Zero same-chain stores within 10 km) (<i>Fairness</i>)	-0.0421** (0.0204)	0.0265 (0.0173)	0.166*** (0.0445)	-0.0361 (0.0448)
Chain Fixed Effects	X	X	X	X
Number of observations	3,810	5,605	9,976	3,288

Dependent Variable:	Log Prices in Store s in Years 2006-08 and 2012-14			
<i>Panel B. Within-Chain Learning</i>				
Log (Elast. / (Elast.+1)) in Store s	0.0738*** (0.0227)	0.143*** (0.0313)	0.186*** (0.0430)	0.121** (0.0548)
Log (Elast. / (Elast.+1)) in Store s * (Years 2012-14) (<i>Learning</i>)	-0.0197 (0.0185)	-0.0280 (0.0184)	0.218*** (0.0353)	0.109** (0.0528)
ChainXPeriod Fixed Effects	X	X	X	X
Number of observations	6,972	10,312	17,106	6,024
Number of stores	3,486	5,156	8,553	3,012

Notes: Throughout, the first stage uses within-chain variation in income and log(elasticity/(elasticity+1)) as in Table 5 columns (6)-(8) using all stores. Standard errors are block bootstrapped at the parent_code*chain level. In Panel B, each observation is a store-level log price in 2008-2010 or 2012-2014. Only stores present in both periods are included.
